The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5649.

Back Issues of the Journal: Published monthly since 1911, a limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Quality of Death Certificates in Valencia, Spain

FERNANDO G. BENAVIDES, MD, PHD, FRANCISCO BOLUMAR, MD, PHD, AND RAFAEL PERIS, MD, PHD

Abstract: Certificates of 1,454 deaths occurring over 11 months were retrieved from the Civil Register in Valencia, Spain. Relevant medical information was systematically gathered from hospital records, questionnaires, and Coroner reports. We compared the underlying cause of death (UCD) from the original death certificate, and a reference cause of death (RCD) determined by a panel of experts based on all available information. Overall, 80.2 percent of the certificates were concordant for disease category, but there was a great disparity among some specific disease categories. (*Am J Public Health* 1989; 79:1352–1354.)

Introduction

The quality of mortality statistics has been studied frequently.[1–6]

While mortality statistics are commonly used both for research and administrative purposes in Spain, their reliability has not yet been studied in full detail. This is an important omission; the first studies in this field were carried out in other countries as early as the 1940s.[7–9]

To date, studies of the quality of the registered causes of death have been based on death certificates selected either because stated causes were specific diseases or because of the availability of information required to test the concordance of the death certificate.[10–14] In order to minimize such selection biases, the present investigation was population-based.

Methods

All death certificates for the 255,866 residents in the catchment area of the Teaching Hospital in the region of Valencia, Spain from February–December 1984 were obtained from the Civil Register. For the resulting 1,454 certifications, we systematically reviewed autopsy findings, questionnaires addressed to the certifiers, and hospital records.

The monthly search for this information started in the Teaching Hospital. If hospital records corresponding to each death were available in the first week of the search, and the last inpatient summary had been completed within the three months prior to death, the search for clinical information was concluded.

When results of first step were negative, a questionnaire (based on work by Moriyama, *et al.*[15]) requesting clinical information about the death was sent to the certifier in the first week of the month following the death, and a list of all such deaths was sent to the Hospital Records departments of all the other hospitals in the city.

Finally, records were obtained from the Coroner's Office for those deaths which had been certified by a Coroner.

All the available information was reviewed separately by two specialists in Internal Medicine, who were not conversant with the information recorded in the original death certificate. Kappa index of agreement between the two reviewers was 0.78 (confidence intervals 0.76, 0.81). When internists opinions did not coincide, a third specialist was called in to review the information and thus provide a conclusive decision. All three specialists had been trained previously in certifying procedures by experienced physicians from the Office of Mortality Statistics.

Applying the rules of the ICD-9th revision,[16] professional coders selected the underlying cause of death (UCD) from each original certificate and the reference cause of death (RCD) from each standard certificate produced by the internists.

Using two by two tables for each cause and for each group of causes, the Detection Rate (DR),* and the Confirmation Rate (CR),** were computed working at a three-digit level of ICD-9th codes.

From the initial 1,454 certificates, clinical information was obtained for 1,176 deaths; in the remaining 278 deaths neither clinical records were available nor were questionnaires answered. Out of the 1,176 deaths, 108 (9.2 percent) were not included in the study because the medical reviewers considered the clinical information inadequate to test the concordance. Therefore, the final number of deaths studied was 1,068 (73.5 percent of the initial sample).

Results

In 50.9 percent of the 1,068 deaths, clinical information was obtained only from hospital records, in 27.7 percent only from questionnaires, and in 11.9 percent from both sources. Coroners' reports provided the remaining 9.4 percent of the information, of which 1.9 percent had also hospital records. The total number of deaths with hospital records amounted to 692. In 40 cases, autopsies were carried out by hospital pathologists. Of the 692 deaths with information obtained through hospital records, 562 (81.2 percent) took place in hospitals.

According to the completed questionnaires, the duration of the professional relationship between the certifier and the deceased had lasted less than 24 hours in 29.2 percent of the cases. When deaths occurred in hospitals, this percentage increased to 53.7 percent; when deaths occurred at home, it decreased to 17.9 percent.

Agreement between Detection and Confirmation Rates did not vary by duration of professional relationship, by place

*Detection Rate equals the number of concordant deaths according to a particular disease category divided by the number of standard death certificates from the same disease category.

**Confirmation Rate equals the number of concordant deaths according to a particular disease category divided by the number of original death certificates from the same disease category.

TABLE 1—Percentage Agreement (with 95% Confidence Intervals) of Detection and Confirmation Rates by Place of Death, Duration of Professional Relationship and Sources of Information

Place of death	N	Agreement Indexes (%)	95% CI
Home	426	80.5	76.7, 84.2
Hospital	642	80.1	77.0, 83.1
Duration of professional relationship			
>3 months	215	81.8	76.7, 86.9
<3 months	85	82.4	74.3, 95.5
<24 hours	124	81.5	74.6, 88.3
Sources of information			
Clinical records	692	79.1	76.1, 82.1
Questionnaires (only)	296	82.1	77.7, 86.5

of death, and by sources of information (Table 1).

The agreement indexes for all causes were 80.2 percent both for the detection and confirmation rates, as shown in Table 2.

The agreement indexes, DR and CR, for the major categories of causes of death can also be found in Table 2. They are highest for tumors (DR = 89.9 percent and CR = 95.3 percent) and circulatory diseases (DR = 87.6 percent and CR = 80.5 percent).

Agreement indexes for the rest of groups of causes were questionable, due to the small number of deaths on which they were based. Table 3 displays the matrix plotting underlying cause against reference cause.

As regards specific tumor sites, the highest indexes of agreement were those for lung cancer (DR = 84.6 percent and CR = 91.7 percent) and breast cancer (DR = 88 percent and CR = 95.7 percent). Conversely, liver cancer showed very low rates of agreement (DR = 53.8 percent and CR = 37.9 percent), and colon cancer showed indexes below 80 percent but of a very similar nature (DR = 75 percent and CR = 71.4 percent).*

*Data available on request to author.

Agreement indexes for circulatory diseases varied greatly. Hypertensive disease produced low indexes of agreement. Arteriosclerosis gave quite similar results, with even lower indexes (DR = 19.2 percent and CR = 21.7 percent). Acute myocardial infarction showed a DR of 75.5 percent and a CR of 53.7 percent and the intra craneal haemorrhage a DR of 84.2 percent and a CR of 55.2 percent. However, the overall agreement in this group was over 80 percent.*

Discussion

In these data, mortality statistics as a whole appear to be reasonably reliable: 80.2 percent of the certificates showed good concordance. This figure lies somewhere within the range of results obtained by Alderson[4] in the Oxford Record Linkage Study Area (61 percent of agreement) and by Faire[5] among Swedish twins born in 1901–25 (DR = 94.9 percent and CR = 95.6 percent) (our estimate from their figures).

When comparing our population based results with those of Kircher in Connecticut,[14] based on autopsies, we found his confirmation rates to be lower than ours for neoplasms, circulatory diseases, and respiratory diseases (85 percent versus 95.3 percent; 75 percent versus 85.5 percent and 31 percent versus 60.3 percent, respectively). These differences might be explained, at least to some extent, by the fact that when only autopsies are used to validate death certificates, a higher level of disagreement is to be expected as autopsies are carried out mainly on diagnoses that appear uncertain.

It is interesting to note that in our study 13 deaths initially certified as due to cancer were reclassified after reviewing the available clinical information, and 30 deaths initially assigned to groups other than tumors were then reclassified as due to cancer. This finding suggests that mortality from cancer was underreported by 6.1 percent, a figure that lies between the value of 5 percent found by Griffith in England and Wales[17] and the value of 10 percent observed by Engel in Georgia.[18]

Percy, *et al*,[6] estimate a DR and CR of 82.7 percent for tumors in the USA, a value close to ours as regards DR but lower in respect to CR. Our results are relatively close to those obtained by Faire[5] in Sweden with a DR of 98.2 percent and a CR of 99.5 percent.

TABLE 2—Agreement Indexes for the Underlying Causes of Death, ICD-9A Main Category

Disease Category	UCD(*) N	RCD(**) N	Agreements N	Detection Rate %	Detection Rate SD	Confirmation Rate %	Confirmation Rate SD

With respect to mortality due to cardiovascular diseases, our indexes lie between those obtained by Engel[18] (DR = 69.0; CR = 75.6) and those found by Faire[5] in Sweden (DR = 92.4; CR = 88.8).

It has been argued that concordance indexes might depend on the precision and completeness of the information used by the reviewers to establish the standard cause of death. In our case, the influence of what has been called reviewer bias does not seem to play an important role, as additional information obtained after the death usually comes from autopsies and the number of these in our area was dramatically low.

It has also been argued that reviewers might have access to clinical records to which medical certifiers did not have access. But this does not accord with the fact that in our study 81.2 percent of the deaths with clinical records available took place and were certified in hospitals. However, even if this were the case, it would lead to a real discrepancy since the reviewers would have been able to establish the cause of death more accurately.

On the contrary, if the medical certifiers had access, the discrepancies would be spurious. Nevertheless, 72.3 percent of the information used to test the degree of concordance came from hospital records and forensic reports and thus was equally available for both certifiers and reviewers.

Some information was obtained only from questionnaires. This presented the problem of the reviewing doctors not having access to any more information than that which was transcribed. However for 70.5 percent of the completed questionnaires, corresponding to deaths at home, there was presumably no more information than that which appeared on the questionnaires, as the systematic search for the clinical records of these cases was negative. However, the possibility that a crucial piece of information which might have been known to the medical certifier did not appear in the records, although remote, cannot be ruled out in this sort of study.

ACKNOWLEDGMENTS

We thank Dr. S. Guiral and E. Gonzalez for their help with data collection; Drs. V. Arraez, L. Jimenez and P. Bordes for their work in the panel of specialists; and A. Nolasco for computer programming. This work was partially supported by the Spanish Medical Research Fund (FIS) (Grant 84/1933).

Risk Reduction among Intravenous Drug Users in Amsterdam under the Influence of AIDS

J.A.R. van den Hoek, MD, H.J.A. van Haastrecht, MS, and R.A. Coutinho, MD, PhD

Abstract: We evaluated the impact of a needle/syringe exchange program among 263 drug users in the period December 1985 to April 1988. Participants in this study were asked about their risk-behavior at three different visits. We found no increase in the proportion injecting drugs or in the frequency of intravenous drug use. A strong decrease in borrowing and lending of used needles/syringes was found and this behavioral change was not dependent on learning human immunodeficiency virus (HIV) serostatus. Although use of the exchange program increased over time, reduction in needle sharing was mainly an effect of the study with only a limited impact of the exchange program. We conclude that ample provision of needles and syringes is an important starting point but in itself not enough to produce the necessary drastic change in risk behavior. Intensive counseling of the drug user is also needed. (*Am J Public Health* 1989; 79:1355–1357.)

Introduction

In the absence of an effective treatment or vaccine, control of infections with the human immunodeficiency virus (HIV) relies on efforts to reduce risk behavior. To control the spread of HIV among intravenous drug users (IVDUs) a prevention campaign was launched in Amsterdam, The Netherlands.[1]

Leaflets with information on HIV and its transmission are distributed and meetings are held for workers in the drug field and for drug users. As sharing of needles and syringes is considered to be the main transmission route among intravenous drug users,[2] a needle/syringe exchange program was organized as part of this campaign. The exchange program started on a small scale in 1984; by 1987 700,000 syringes and needles were provided through existing social agencies and treatment facilities.[3] To evaluate the impact of the campaign, a longitudinal study was undertaken. The objectives of this study are to determine whether drug users are able to change their risk behavior and if risk reduction occurred, whether this can be ascribed to the prevention campaign or to the effect of serological testing and counseling during the study.

Methods

Participants were recruited at six methadone outposts and the weekly sexually transmitted disease clinic for drug-using prostitutes. None of these facilities are drug free. As one of the aims of the study was to find out whether the syringe exchange program could lead to an increase in intravenous drug use, ex-intravenous drug users and non-intravenous drug users were also invited to participate.

Participation was voluntary and, after extensive information had been given, informed consent was obtained. A blood sample was taken and participants interviewed using a standard questionnaire which included questions concerning clinical symptoms, medical history, lifestyle, use of oral and intravenous drugs (methadone included), and prostitution. Participants were asked to return for a follow-up visit every four months. At each occasion, the same interview and a blood sample were taken. To encourage continued participation 25 Dutch guilders ($12 US) were paid per follow-up visit.

From December 1985 to March 1988, 569 drug users without HIV-related disease entered the study, approximately one-seventh of the drug users visiting the methadone posts and the special STD-clinic in that period; 263 (46 percent) returned for at least one follow-up visit before July 1988. No difference was found in age, gender, nationality, and history of prostitution between the 263 drug users who returned and the 306 who did not return for a follow-up visit. However, among those who returned, a higher percentage was infected with HIV (33.1 percent vs 19.0 percent, 95% CI of difference = 6.9, 21.3), had been staying in Amsterdam longer than one year (88.2 percent vs 78.4 percent, 95% CI of difference = 3.8, 15.8), and had a history of current IV drug use (71.9 percent vs 53.9 percent, 95% CI of difference = 10.2, 25.8).

We compared results of the interview regarding the intravenous drug use behavior in the six-month period preceding the intake and during the follow-up period.

Since participants did not return for follow-up regularly, only those with an interval of three to six months between the visits were selected for study. As a result, 233 participants remained whose second visit data could be analyzed. The mean period between the first and second visit was 127 days (SD ± 20). A sub-group of 165 participants made a third visit, enabling us to study the risk behavior over a longer period of time. The mean duration between the second and third visit was 123 days (SD ± 20). There was no difference in age, gender, duration of drug use, nationality, and HIV-prevalence between the first-, second- and third-visit groups.

To determine the effect of infection status on risk behavior, three different groups were distinguished among 140 current intravenous drug users: those participants who did not know their serostatus (17); those who knew that they were infected with HIV (39); and those who knew that they were uninfected (84). Forty-nine other current users were excluded because knowledge of serostatus was too close to their second visit or no information was available about the date of disclosure.

The average time between intake and disclosure of the serostatus was 32 days (SD ± 7), and 97 days (SD ± 19) between disclosure and second visit. Only data of the first and second visit were studied; at the third visit the number of persons available was too small.

Recruitment into the study took place over a period of 27 months. Thus we could also study the risk behavior of current intravenous drug users at intake over time. We divided the 27-month intake period into four periods of equal length (207 days). The HIV antibody seroprevalence of the four intake-groups defined their risk category.

χ^2 test with Yates' correction and χ^2 for trend in proportions were used for testing group differences and behavioral changes. Log-linear modeling[4] was employed for testing differences in behavioral changes between subgroups and for differentiating between effects on behavior caused by the prevention campaign (time effect) or by the study itself (study effect). Serological tests used for HIV-ab testing were ELISA (enzyme-linked immunosorbent assay) and confirmation of positive specimens was performed by immunoblotting and competitive ELISA.[5]

Results

Of the 263 study participants, 140 were male and 123 female. The mean age was 29.1 years (SD 5.4). Seventy-one percent were Dutch, 20 percent German, and 9 percent another nationality. Two hundred and thirty-three of the 263 participants had a history of intravenous drug use at entry into the study; 189 of them used drugs intravenously at least once during the six months preceding intake (current intravenous drug users). Heroin in combination with cocaine was injected by 58 percent of the current users, 21 percent used heroin alone, 7 percent cocaine alone, and 5 percent amphetamine alone. At entry into the study, 87 (33 percent) of the 263 participants had antibodies to HIV (36 percent of the men and 30 percent of the women). None of those 87 HIV-infected had severe HIV-related disease (acquired immunodeficiency syndrome or AIDS-related complex).

The proportion of current intravenous drug users who obtained their needles and syringes exclusively through the exchange program increased from 31.2 percent at the first visit to 52.3 percent at the third visit (Table 1), although the proportion of all drug users reporting using drugs intravenously and the frequency of injecting did not differ over time. Borrowing and lending needles and syringes among current users decreased sharply over time. The behavioral change occurred in both men and women, and in all nationality groups.* Decrease in needle sharing occurred to the same extent regardless of knowledge of serostatus (Figure 1).

The borrowing behavior at intake of current intravenous drug users was comparable over time although those who entered the study later lent their needles/syringes less often to others than those who entered in the beginning (Table 2). The use of the exchange system and single syringe use increased over time. The HIV-prevalence of those entering the study decreased over time.

To investigate the relative importance of a study-related (follow-up) effect versus a time-related (prevention campaign) effect, the effects were log linearly modeled and tested.* The time variable was dichotomized at the midpoint of the intake period.

The reduction in borrowing was merely a study effect, being unrelated to time. The likelihood ratio statistics of lending were significant for both study and time effects indicating a strong study-related reduction in lending behavior independent from the mere time effect. The increase in the use of the exchange system appeared mainly a time-related effect. The increase of single needle/syringe use appeared to be both study-related and time-related. These data are also suggested by inspection of Tables 1 and 2.

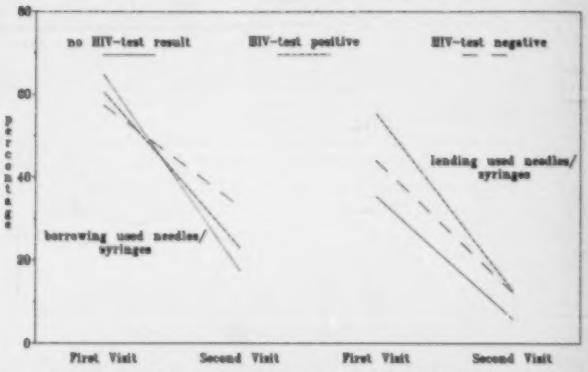

FIGURE 1—Current Intravenous Drug Users Engaged in Needle/Syringe Sharing by HIV-ab Test Result in Amsterdam, December 1985–July 1988

Discussion

The results of this follow-up study clearly show that IV drug users are able to reduce their sharing of needles/syringes, the main risk factor for contracting HIV in this group. Risk reduction among IV drug users has also been observed in New York City,[6] and in various retrospective studies.[7] A drawback of retrospective studies is that participants may tend to make the past look worse and the present better.

There was a sharp increase in the proportion of intravenous drug users in Amsterdam making exclusive use of the exchange program to obtain clean needles and syringes, apparently reflecting the effect of the prevention campaign.

We found no evidence that the non-intravenous drug users in our study group started intravenous use in spite of the availability of clean needles and syringes. Apparently the way in which drugs are used is rather stable.

Although an increasing number of intravenous drug users in Amsterdam obtain their needles/syringes through the exchange program, the impact of this prevention campaign on

risk behavior still leaves something to be desired. Borrowing used needles and syringes—at least once in the prior six months—was as often reported by those who entered our study at the end in 1986 as it was in 1988, even though this last intake group had a lower HIV-prevalence indicating they had been less at risk for HIV-infection. As we asked only whether the participants borrowed at least once, it may be that the frequency of borrowing diminished over time.

However, to be effective, risk reduction has to be total. Such a strong behavioral change was found only among the intravenous drug users who participated in the follow-up study.

The extent of behavioral change that we found during follow-up did not depend on learning one's infection status. In contrast, studies of homosexual men have found that seropositives changed their behavior more than seronegatives and untested comparison groups.[8] Apparently, among drug users counseling has a more important influence. From our results it seems that the needle/syringe exchange program and a testing program on a voluntary basis can be expected to have strong influences on risk behavior only when such programs are combined with intensive counseling.

We conclude that the Amsterdam AIDS prevention campaign did not increase the intravenous use of drugs, as is often feared, but did not automatically lead to complete change of risk behavior among intravenous drug users. To obtain such a maximum effect, intensive counseling of drug users seems indicated. Proposals have now been formulated to start with two special teams of counselors, one for drug users who participate in the methadone programs and one for those drug users who are not in contact with treatment programs.

We recognize that we have studied risk reduction among a selected group that may not represent all drug users in Amsterdam, but this is inevitable in all studies of drug users. In addition, the results are based on self-reporting. An objective measure of self-reported risk reduction is a reduced attack rate of HIV infection over time. As of July 1988, we have observed 10 seroconversions among 148 seronegative drug users with a history of IV drug use in the previous five years. The attack-rate (Kaplan-Meier) after a follow-up of one year was 7.3 percent (95% CI: 2.6, 12.0). The number of seroconversions in the follow-up period is still too small to enable us to do a reliable comparative study of the attack rate over time in relation to this process of risk reduction.

Impact of the AIDS Epidemic on Morbidity and Mortality among Intravenous Drug Users in a New York City Methadone Maintenance Program

PETER A. SELWYN, MD, MPH, DIANA HARTEL, MPH, WILLIAM WASSERMAN, MPH, AND ERNEST DRUCKER, PHD

Abstract: To examine the impact of the AIDS epidemic on morbidity and mortality in a defined population of intravenous drug users, we analyzed overall and cause-specific death rates, AIDS incidence, and acute medical hospitalizations among patients in a long-term methadone maintenance program in New York City for the years 1984 through 1987 (midyear population for each year 828 to 891; demographic characteristics did not differ). The number of deaths while in treatment increased from 11 (13.3/1000) in 1984 to 39 (44.2/1000) in 1987. Deaths from AIDS increased from 3.6/1000 to 14.7/1000, deaths due to bacterial pneumonia/sepsis from 3.6/1000 to 13.6/1000; deaths from cirrhosis, drug overdose, trauma, and other causes remained relatively stable. AIDS incidence rose from six cases/1000 in 1984 to 20.4.1000 in 1987. Hospitalizations for AIDS, pneumonia, tuberculosis, and endocarditis/sepsis increased from 84.9/1000 in 1986 to 144.8/1000 in 1987.

These data suggest that the AIDS epidemic has had a profound effect on patterns of morbidity and mortality among intravenous drug users in this methadone program population. Drug treatment programs may be important sites for targeting clinical services for drug users with AIDS, although the increasing burden of AIDS-related disease will require expansion of existing funding and treatment resources. (*Am J Public Health* 1989; 79:1358–1362.)

Introduction

Intravenous drug users have historically been known to be at increased risk of death from drug overdose, alcoholism, trauma, and infectious causes.[1–4] Since the early 1980s, the acquired immunodeficiency syndrome (AIDS) has become a new and increasingly important cause of death among drug users, especially in New York City.[5–7] In addition, New York City surveillance data demonstrate a concurrent increase in pneumonia hospitalizations and deaths among narcotics addicts,[5,8,9] which may reflect additional consequences of human immunodeficiency virus (HIV) infection in this population.[5,7–11]

It has been estimated that there are between 1.1 and 1.3 million intravenous drug users in the United States, with over 200,000 in the New York City metropolitan area alone.[6,12] In New York State, there are currently over 35,000 patients enrolled in methadone maintenance treatment programs.* Historical patterns of morbidity and mortality among patients in methadone maintenance treatment are well described[13–19]; however, most of this literature predates the AIDS era and does not address the impact of the current epidemic of HIV infection and AIDS on such populations.

We examined AIDS incidence rates, overall and cause-specific mortality rates, and medical hospitalization patterns among a defined population of intravenous drug users in a long-term methadone maintenance treatment program in the Bronx, NY, from 1984 through 1987.

Methods

This study was conducted at the Drug Abuse Treatment Program of Montefiore Medical Center, Bronx, NY, which operates three outpatient methadone maintenance clinics for chronic opiate addicts. The treatment program, which serves a population of approximately 900 current and former intravenous drug users, provides on-site primary medical care for all patients, as well as methadone maintenance and support services.

In late 1983, centralized registries were established and maintained by program medical staff for recording all AIDS diagnoses and deaths among program patients; in late 1985, a log was established and reviewed weekly to monitor all hospitalizations occurring in the patient population. AIDS cases were identified both through ongoing patient contact with on-site medical services at the methadone program and through review of hospital records for suspected cases. Causes of death were identified and verified (by the first author) for all patients dying while in treatment, through a review of hospital records, death certificates, and medical examiners' reports for cases in which postmortem examinations were performed. Surveillance for hospitalizations was facilitated by inpatient follow-up of patients referred by medical staff for hospital admission, and by the requirement that hospital staff must contact clinic staff in order to verify methadone dosages for hospitalized patients.

Overall and cause-specific mortality rates per 1000 for methadone program patients dying while in treatment were calculated for each calendar year from 1984 through 1987, using the midyear population census as the denominator for each year. Person-time death rates were also calculated based on time spent enrolled in the methadone program and are expressed as deaths per 1000 person-years. Deaths were classified as due to AIDS in cases with either an ante- or postmortem AIDS diagnosis, in which AIDS was listed as a cause of death; deaths were ascribed to other causes only after AIDS diagnoses had been excluded through review of all available information. In order to evaluate the possible relation between HIV infection and causes of death other than AIDS itself (e.g., deaths from bacterial pneumonia or sepsis), we examined the HIV serologic status of the subgroup of deceased patients who had also been enrolled in a

seroprevalence and longitudinal study of HIV infection initiated in 1985 at the same clinic site.[20] This ongoing study, aspects of which have been previously described,[20–22] involved voluntary, confidential HIV antibody testing and clinical/research follow-up for a cumulative cohort of over 600 patients in the Montefiore program. The overall HIV seroprevalence level in the cohort has been approximately 40 percent.[20–22] As described elsewhere, seroprevalence study participants and non-participants did not differ with respect to standard demographic variables or the length of time in methadone treatment.[20–22] While the aim of the seroprevalence and longitudinal study has been to examine the natural history of HIV infection, that of the current analysis was to evaluate the impact of the epidemic of AIDS and HIV infection over time on a defined population in drug abuse treatment.

The incidence of AIDS in the entire study population was calculated for each year in the four-year period, with the occurrence of incident cases of AIDS expressed both as a proportion per 1000 persons and as a rate per 1000 person-years in treatment. In addition to incident AIDS cases arising out of the clinic population, yearly trends in the number of patients already diagnosed with AIDS and referred to the program for drug abuse treatment were monitored. To ensure uniformity of definitions and reporting, the original[23] and not the revised[24] Centers for Disease Control (CDC) AIDS surveillance definition was used for all four years of the study period as the standard for AIDS diagnoses.

Medical hospitalization logs, which were available only for the latter two full years of the study period, were reviewed for the years 1986 and 1987. Hospitalizations were classified by primary diagnosis into the most frequently occurring categories, and the frequencies of hospitalization for different diagnostic categories were compared for the two 12-month periods. Diagnoses were confirmed through review of hospital records. Hospitalizations for all AIDS-specific opportunistic infections were classified as due to AIDS. Elective admissions for inpatient alcohol or drug detoxification were excluded from this analysis. Hospitalization events by year were calculated for each year with the total number of patients enrolled in the program each year as the denominator.

As noted above for the determination of AIDS incidence and death rates, only those events are included which occurred while patients were enrolled in the methadone program; the analysis does not reflect any additional outcomes which may have occurred among patients leaving the program during the study period. Estimates should therefore be considered minimum estimates. The midyear patient population was chosen as the denominator for incidence calculations for each year since there was movement in and out of the program but the number of persons entering and leaving treatment was balanced for each year of the study period. An examination of time spent by patients in the program each year indicated that person-time did not differ between years, with individuals remaining in the program for a mean of approximately 300 days each year. Analyses of changes in incidence rates over the four-year study period were based on point and interval estimates of rate differences.[25] In addition, trends over the four years in AIDS incidence and overall and cause-specific mortality rates were examined.

Results

From January 1, 1984 through December 31, 1987, a total of 1,598 patients were treated: 59 percent male, 20 percent White, 27 percent Black, 52 percent Hispanic (primarily Puerto Rican), and 1 percent classified as "other." Racial and gender distributions did not differ by year for any of the four years. The median age of the entire patient population as of January 1, 1984, was 32 years, with the central three-fourths of all patients each year between the ages of 30 and 45. The overall age distribution (by year of birth) was fairly constant from year to year. The midyear patient census for each of the four years ranged from 828 to 891 (Table 1). Of the 1,598 patients treated in the program during the study period, 844 (53 percent) were enrolled prior to 1984, of whom 416 (49 percent) remained continuously enrolled through the end of 1987. Seven hundred and six patients were newly admitted during the four years, and 48 patients were readmitted after having left treatment before 1984. The number of patients discharged from treatment each year ranged from 162 to 197; discharged patients did not differ by year with respect to race, gender, or age, nor was there a statistically significant trend in drop-out rates during the study period.

Death Rates

A total of 94 patients died while in treatment during the study period (Table 1). The yearly number of deaths increased steadily from 1984 through 1987, even though the midyear population each year remained stable. The proportion dying (based on the mid-year population size) increased from 13.3/1000 in 1984 to 44.2/1000 in 1987. By person-time analysis, there were 12.9 deaths/1000 person-years in 1984, compared with 44.0/1000 person-years in 1987.

Causes of Death

The crude mortality rate from AIDS in 1984 was 3.6 per 1000 patients. This rate increased steadily through the study period to 14.7 per 1000 in 1987. Deaths from pneumonia, endocarditis, and bacterial sepsis combined—in patients without any diagnosis of AIDS—also rose from 3.6 per 1000 in 1984 to 13.6 per 1000 in 1987. Smaller or minimal increases were seen for deaths from cirrhosis, drug overdose, trauma, and other causes, which were less frequent causes of death. Cause-specific death rates (person-time) among methadone program patients are graphically displayed in Figure 1. The number of deaths due to AIDS rose from 3.5/1000 person-years in 1984 to 14.7/1000 person-years in 1987 (difference 11.2/1000, 95% CI: 2.2, 20.0). Similarly, there was an increase in death rates from pneumonia, endocarditis, and bacterial sepsis, which together rose from 3.5 to 13.5/1000 person-years from the first to the fourth year of the study period (difference = 10.0, 95% CI: 1.4, 18.6). Deaths due to alcoholism/cirrhosis and drug overdose remained relatively constant between 1984 and 1987 (3.5 to 5.7/1000 person-years); death rates from trauma, including homicide, suicide, and vehicular trauma, showed a slight increase during the

TABLE 1—Deaths by Year among Montefiore Methadone Program Patients, New York City, 1984–87

	1984	1985	1986	1987
Midyear Census	828	875	891	882
Person-years	850	864	873	886
Mean Days Observed	296	300	294	300
Number of Deaths	11	15	29	39
Deaths per 1000	13.3	17.1	32.5	44.2
Deaths/1000 person-yrs	12.9	17.4	33.2	44.0*

*Rate difference 1987–1984 = 31.1 (95% confidence interval: 15.3, 46.9).

FIGURE 1—Causes of Death in Montefiore Methadone Program Patients, 1984–87

study period (2.4 to 6.8/1000 person-years). The final category, which also showed a slight increase (0 to 3.4/1000 person-years), was defined as "other," and included deaths from renal failure, pulmonary embolism, bleeding diatheses, stroke, and neoplasms.

Analysis of the HIV serologic status of the subgroup of deceased patients who had been enrolled in the HIV seroprevalence/longitudinal study, as described above, indicated that of nine patients with known serologic status dying from bacterial pneumonia, endocarditis, or sepsis, all were HIV seropositive. In contrast, of 12 patients with known HIV serologic status dying from cirrhosis, overdose, or trauma, 4 (33 percent) were seropositive and 8 (67 percent) seronegative. Of two patients with known serologic status dying of causes classified as "other," both were HIV seropositive. Decedents enrolled in the seroprevalence/longitudinal study did not differ from those in the larger clinic population demographically or by the length of time in methadone treatment.

Incidence of AIDS

The number of incident cases of AIDS newly diagnosed each year increased from five in 1984 to 18 in 1987 (Table 2). The crude annual incidence of AIDS rose from 6.0/1000 in 1984 to 20.4/1000 in 1987. The rate by person-time increased from 5.9/1000 person-years to 20.5/1000 person-years in 1987. In addition to incident cases of AIDS occurring in the treatment program population, 16 additional patients already diagnosed with AIDS were enrolled for treatment during the study period, with a steady increase in such referrals from the first to the fourth year. These patients are excluded from the calculation of AIDS incidence but included in the calculations of hospitalizations and deaths over the four years.

TABLE 2—AIDS Cases among Montefiore Methadone Program Patients, 1984–87

AIDS cases/1000 person-yrs	5.9	9.3	12.7	20.5*
Referred to methadone program after AIDS diagnosis	1	3	5	7

*Incidence rate difference for 1987–1984 = 14.6 (95% confidence interval: 3.8, 25.4).

Hospitalizations

Table 3 presents the frequency of hospitalizations occurring among the Montefiore program patients for different indications during the successive 12-month periods of 1986 and 1987. In 1986, there were 219 hospitalizations, or 202 per 1000 patients; in 1987 there were 269 hospitalizations, or 250 per 1000. A net increase of 71 percent in the frequency of hospitalizations from 1986 to 1987 was observed for AIDS, pneumonia, tuberculosis, and endocarditis/sepsis, which collectively increased from 85 to 145 hospitalizations per 1000 patients over the two years. All other categories showed either minimal increase, no increase, or decrease between the two years.

Discussion

These data document a dramatic threefold increase in overall mortality rates and AIDS incidence and mortality rates from 1984 through 1987, among intravenous drug users in a New York City methadone maintenance treatment program. The parallel increase in deaths from bacterial infections, in patients not diagnosed with AIDS, is consistent with New York City mortality data from the same time period which suggest that such deaths are indeed HIV-related and must be considered in any assessment of the impact of the AIDS epidemic among drug users.[5,7–9] It is noteworthy that among the subgroup of deceased patients with known HIV serologic status, all the bacterial infection deaths occurred in HIV seropositives, compared with only one-third of the deaths due to cirrhosis, overdose, or trauma. These findings are supported by additional data from our prospective studies of HIV infection in the same methadone program population, in which we have observed both a fivefold increased incidence of bacterial pneumonia and an increased death rate from bacterial pneumonia and sepsis in HIV seropositive

versus seronegative intravenous drug users within the cohort.[21,26]

Previous studies of mortality patterns and rates among intravenous drug users consistently suggested both that death rates among addicts were higher than among the general population and that two-thirds or more of drug user deaths were specifically related to drug overdose, violence or trauma, or alcoholism.[1–4,15–19,27–33] Observed annual death rates in such studies, most of which predated the AIDS era, have ranged between approximately 8 and 16 per 1000.[4,17,18,27,30] Several studies of mortality rates among patients in methadone maintenance programs in the 1970s indicated similar yearly rates, all under 16 per 1000.[16–19] Of note is the fact that the pattern of deaths for the year 1984 in our population was comparable to these historical observations from the pre-AIDS era: the overall level in 1984 was 13.3 per 1000, and close to half of the deaths were due to cirrhosis, overdose, or trauma.

However, by the end of 1987, deaths had increased to 44.2 per 1000, with only 28 percent of deaths due to these causes, and 64 percent of deaths due to AIDS or bacterial infections. Thus, the advent of AIDS has introduced a new risk of alarming magnitude. Also of note regarding causes of death in our study was the small increase in deaths in the "other" category, which included deaths from renal failure and bleeding diatheses, among other causes; in at least two of these cases, the patients were suspected of having HIV-related nephropathy or HIV-related thrombocytopenia, respectively, suggesting that HIV infection may have been implicated in these deaths as well. Further study of larger populations is required to elucidate the relation between HIV infection and less common modes of death such as these; however, it is of interest that New York City vital statistics data indicate a similar increase in such miscellaneous causes of death among drug users over the same interval in which death rates from AIDS and bacterial infections were found to rise more dramatically.[5,8,9]

In addition to the striking increases in mortality among patients in our methadone program population, the increasing incidence of AIDS has generated significant morbidity as well. The rate of 20.4 new cases per 1000 persons in 1987 is an order of magnitude higher than an estimate derived for intravenous drug users in New York in 1983–84.[6] It must also be recognized that our reported incidence is an underestimate of the total number of cases which could now be classified as AIDS, since we intentionally used the more restrictive original CDC AIDS case-definition[23] in order to maintain uniform reporting criteria throughout the study period. While we do not therefore have systematic data regarding the increased number of AIDS cases which would be expected under the revised case-definition criteria,[24] clinical experience involving our patient population has suggested that use of the revised criteria would expand the group of AIDS-diagnosed patients by approximately 30–40 percent (unpublished data). This estimate would be in the same range as what was recently calculated by the CDC concerning the percentage of AIDS cases among intravenous drug users in 1988 meeting only revised case-definition criteria.[34]

For more than 2 percent of all patients in the methadone program population per year to be newly diagnosed with AIDS has had important implications for patient care and clinical practice. HIV infection and AIDS have clearly become the preeminent health problems of our patient population, affecting all areas of treatment, including medicine, nursing, counseling, and administration. Few, if any, other areas of the health care system are now being faced with such a high concentration of patients with or at risk for HIV infection; indeed, drug treatment programs may be among the only clinical settings in which the entire patient population is defined by a history of high-risk behavior for HIV infection. Observations that 50 percent or more of intravenous drug users in New York are already infected with HIV,[35,36] and data from a 1985 seroprevalence study in our own population indicating close to a 40 percent prevalence of HIV antibody,[20–22] suggest that any such treatment program for drug users cannot help but be transformed by the consequent impact of AIDS on its patient population. This trend has been amplified by the acceptance into drug treatment of new patients from hospital AIDS units, where fewer than 30 percent of drug users newly diagnosed with AIDS have been found to be enrolled in drug treatment programs.[37]

The need to expand the availability of drug treatment in response to the AIDS epidemic has been stressed repeatedly.[7,12,38–42] However, our data suggest that in order to deal effectively with the AIDS crisis, treatment programs will need to receive much-expanded support for on-site medical services and ancillary care to address the steadily increasing burden of HIV-related morbidity and mortality among their patient populations.

Treatment programs are indeed well-situated to provide comprehensive care to patients with HIV infection, including counseling, family supportive services, and, increasingly, primary medical care interventions such as antituberculous chemotherapy,[22] zidovudine, aerosolized pentamidine, and reproductive health care services for at-risk women. However, the growing volume of methadone treatment program patients with AIDS and HIV-related conditions threatens to overwhelm existing drug treatment resources unless structural changes are made to address the new dimensions of these patients' need for care. Such changes should begin with a thorough re-examination of the character and mission of drug treatment programs, including funding, reimbursement mechanisms, staff training and development, need for interdisciplinary collaboration, and the relationship between drug abuse treatment agencies and local and state health departments. Failure to act now may result in a missed opportunity to use a key point of access to intravenous drug users at the center of the expanding AIDS epidemic, and (because of the great stresses which AIDS places on drug treatment program staff) may also lead to the deterioration of existing services.

ACKNOWLEDGMENTS

The authors would like to thank Karen Kennedy, Janice Colley, Anita Iezza, Meera Satyadeo, Anat Feingold, Irene Fleming, Jane Shaw, Rafael Torres, and the staff of Montefiore Drug Abuse Treatment Program for their clinical dedication and help with data collection; Gerald Friedland, Robert Klein, and Ellie Schoenbaum for their review of the manuscript and ongoing collaboration; and Rose Rivera for administrative help with manuscript preparation. This study was supported in part by a collaborative agreement (H62/CCH200714) with the Centers for Disease Control and by grants from the National Institute on Drug Abuse (5 R01 DA04347) and the Aaron Diamond Foundation.

ANA Issues Call for Abstracts of Computer Demonstrations in Nursing

The American Nurses' Association (ANA) Council on Computer Applications in Nursing will sponsor a computer demonstration theater and software exchange at the ANA Biennial Convention in Boston, June 17–19, 1990. The council is now issuing a call for abstracts of demonstrations in computer applications in nursing. All types of nursing software and related hardware and peripherals are being solicited.

The deadline is November 15, 1989 for submission of written abstracts of demonstration requests. Individuals submitting abstracts will be notified of acceptance by December 15, 1989. Attendees are urged to bring software they would like to exchange; diskettes should be formatted using MS-DOS. Several public domain software packages will be available for review and copying. A limited number of blank diskettes will be available on-site for purchase

To obtain special rules on abstract submission as well as information on hardware to be used, contact: Catherine Taylor Foster, PhD, RN, ANA, 2420 Pershing Road, Kansas City, MO 64108. Tel: (816) 474-5720, ext. 326.

Suicide Risk among Women with Alcohol Problems

EDITH S. LISANSKY GOMBERG, PHD

Abstract: The current study compares 301 alcoholic women, ages 20 to 50, interviewed in 21 treatment facilities, and a control group of nonalcoholic women matched for age and socioeconomic status of family of origin. A significantly higher percentage of alcoholic women (40.0% vs 8.8%) reported having made suicide attempts, a difference of 31.2 percentage points (95% CI = 23.9, 38.5). Age comparisons within the alcoholic sample show the percentage of younger alcoholic women attempting suicide to be twice as great as the percentage of the alcoholic women suicide attempters in their forties. Such age differences were not found among the nonalcoholic control group. The findings suggest that youthfulness and alcohol/drug abuse are the critical combination for high risk. Awareness of the suicide attempt risk potential is necessary both for emergency room personnel and for substance abuse facility workers. (*Am J Public Health* 1989; 79:1363–1365.)

Introduction

Almost a century ago, Durkheim's classic work on suicide pointed out that more men than women committed suicide, but that suicide attempts were more frequent among women.[1] There have been attempts to explain this gender difference in terms of sex roles and cultural attitudes.[2–4] Durkheim also noted the relation between suicide and alcoholism and, indeed, suicide is one of the more frequent causes of death among alcoholics.[5–8] This relationship between alcoholism and suicide has been related to depression and other psychiatric disorders, to erosion of social networks, and to disrupted interpersonal relationships.[9–12]

Similar male:female patterns of completed suicide and suicide attempts seem to prevail among alcoholic persons.[13–16] Goodwin concluded that there was an association between alcoholism and suicide among White male alcoholics during the middle years of life, whereas, ". . . attempters generally are younger and are more likely to be women . . ."[17]

A review of the epidemiology of suicide attempts[17] shows the risk years to be the twenties and the same review showed more female than male attempters in the countries and time periods studied. A recent analysis of male and female suicide rates[18] found completed suicide rates are significantly higher for men.

Suicide rates are high among both male and female alcoholics. A recent study of predictors of mortality among women alcoholics found significantly higher mortality for alcoholic women than for the general population of women; "accidents and violence" accounted for 26 percent of the deaths, ranking second as the cause of death in the alcoholic sample.[19] There are few studies of suicide attempts by alcoholics, by women alcoholics, or by women alcoholics of different ages. We studied suicide attempts in alcoholic and nonalcoholic women by age group.

Methods

Three hundred and one White women, admitted to 21 alcoholism treatment facilities in Michigan, completed a one-to-two-week period of detoxification and were then interviewed by trained female interviewers of the Field Office, Institute for Social Research, University of Michigan.

The 21 facilities included inpatient, outpatient, small town, and urban facilities, and the women were referred to the facility by self, physician, family member, the court, friends, etc. All consecutive admissions between the ages of 20 and 50 were asked to participate; refusal rate was 7 percent. All respondents were White because available evidence indicates differences in age, drinking patterns, and alcohol-related problems when White and Black alcoholic women are compared.[20] Age at onset was, inevitably, related to current chronological age, i.e., alcoholic women in their twenties had a mean age at onset of 19.58 years (standard deviation = 3.18); alcoholic women in their thirties reported their mean age at onset as 28.34 years (standard deviation = 5.35); and the alcoholic women in their forties reported mean age at onset as 36.52 years (standard deviation = 5.93).

When 200 of the 301 women in the alcoholic sample had been interviewed, the demographic information was evaluated in order to obtain a nonalcoholic sample of women approximately matched on socioeconomic status. The control women were White, between 20 and 50 years of age, and approximately of the same social class as the alcoholic women. They were selected by nomination; the alcoholic women who remained to be interviewed (100) and women in the local chapters of Alcoholics Anonymous and Women in Sobriety were asked to give the name of an acquaintance or neighbor who was *not* alcoholic. Refusal rate of the nominated women was the same as that of women in treatment; when funding was terminated, interviews had been completed with 34 nonalcoholic women in their twenties, 53 in their thirties, and 50 in their forties. Of these 137 control women, none had ever needed a drink before breakfast and none have ever sought help because of their drinking, three had gotten into trouble at school, one had been arrested for driving under the influence, and one reported that she had "neglected obligations" for two days. Two said that they had once "wanted to stop drinking but couldn't." As a group, however, they were nonalcoholic.

The economic status of family of origin and the white/blue collar status of respondents' parents were similar in the alcoholic and nonalcoholic groups.[21] The control group was also compared with a random sample of women interviewed in an earlier, national survey.[22] When women between the ages of 20 and 50 from the national sample were compared with the present control group on items dealing with psychiatric symptomatology, no significant differences were apparent.*

*Data available on request to author.

The standardized interview schedule include items dealing with demographics; early family experience; drinking history; marital, parenting and employment experience; health; social supports; pregnancies; drug usage; and psychiatric symptomatology. The interview was composed of items culled from several alcoholism study interviews in the Connors Collection of the Rutgers Center of Alcohol Studies, from the Diagnostic Interview Schedule (DIS) of the National Institute on Mental Health, from the Center on Epidemiological Studies Depression Scale (CES-D), and from several earlier surveys conducted at the Institute for Social Research. After field-testing and revising, the interview schedule was reviewed by a panel of three clinicians and a panel of three recovered alcoholic women.[21]

Although alcoholic and nonalcoholic women were matched for age and for socioeconomic status of family of origin, the alcoholic women reported more behavioral, emotional and impulse control problems in childhood and adolescence.[21,23] There are significant differences between the two groups of women in educational achievement, marital history and marital status, and occupational level.[21]

Results

The difference between alcoholic and nonalcoholic women in the proportion reporting any suicide attempt is striking: 40.0% versus 8.8%, a difference of 31.2 percentage points (95% CI = 23.7, 38.5) (Table 1).

Among alcoholic women, suicide attempts were twice as common at ages 20–29 as at ages 40–49. The same age differences, however, did not appear in the nonalcoholic sample. These results do not support the idea that younger women in general are at more risk for suicide attempts than women of other ages.

When the women were interviewed, they were asked about the use of substances other than alcohol, and the alcoholic women reported significantly more often that they had used or were currently using nicotine, prescribed drugs, and banned substances (Table 2). Those who had made suicide attempts were also more likely to have used any of the drug substances asked about. There were too few nonalcoholic women who reported a suicide attempt (N = 12) for meaningful comparisons; it is of interest that those who have made a suicide attempt are also more likely to be users of Valium and sedatives.

TABLE 1—Proportions of Alcoholic and Nonalcoholic Women Reporting Suicide Attempts, by Age

Age (years)	Alcoholic N/Total (%)	Nonalcoholic N/Total (%)	% Difference	95% Confidence Interval
20–29	50/99 (50.5)	3/34 (8.8)	41.7	27.8, 55.5
30–39	46/108(43.0)	5/53 (9.4)	33.6	21.2, 45.9
40–49	24/94 (25.5)	4/50 (8.0)	17.5	5.9, 29.2
All Women	120/301(40.0)	12/137(8.8)	31.2	23.9, 38.5

Among alcoholic women, there was a clear difference in the reported psychiatric symptoms of suicide attempters and nonattempters. Those alcoholic women who have made suicide attempts also reported significantly more tension, indecisiveness, anxiety and nervousness (Table 2). The report on psychosomatic symptoms was mixed: attempters report more dizziness, hand trembling, and headaches than nonattempters but there is little difference between the two groups in loss of appetite, upset stomach, shortness of breath, hives, or sweating hands.

There was a positive but not strong relation between paternal alcoholism and suicide attempts. Of the alcoholic women who made at least one suicide attempt, 63 percent reported a problem-drinking father; among the nonattempters it was 48 percent. Among the nonalcoholic women, 73 percent of attempters reported having had a problem-drinking father; among nonattempters, it was 28 percent. Among the alcoholic women having an older sibling who was a heavy or problem drinker while the respondent was growing up differentiated between those who made at least one suicide attempt and those who did not: 66 percent and 52 percent. It is of interest that maternal alcoholism did not differentiate

TABLE 2—Ever or Current Drug Use and Psychiatric Symptoms Reported by Alcoholic Women, Suicide Attempters and Nonattempters

Drug/Symptoms	Attempters N/Total (%)	Nonattempters N/Total (%)	Difference	95% Confidence Intervals
Drug				
Nicotine	107/120 (89.2)	140/180 (77.8)	11.4	3.1, 19.7
Valium	93/120 (77.5)	106/180 (58.9)	18.6	8.2, 29.2
Stimulants	86/119 (72.3)	91/180 (50.6)	21.7	10.8, 32.6
Sedatives	79/120 (65.8)	74/180 (41.1)	24.7	13.5, 35.9
Marijuana	82/120 (68.3)	77/180 (42.8)	25.5	14.5, 36.6
Psychodelics	54/120 (45.0)	45/180 (25.0)	20.0	9.0, 31.0
Cocaine	51/120 (42.5)	37/180 (20.6)	21.9	11.3, 32.6
Heroin	17/120 (14.2)	7/180 (3.9)	10.3	3.4, 17.2
Symptom				
Feel explosive	59/119 (49.6)	40/178 (22.5)	27.1	16.2, 38.0
Indecisive	51/120 (42.5)	37/179 (20.7)	21.8	11.1, 32.5
Tense and nervous	43/120 (35.8)	31/180 (17.2)	18.6	8.4, 28.8
Fearful, anxious	31/120 (25.8)	22/179 (12.3)	13.5	4.3, 22.8
Difficulty concentrating	38/119 (31.9)	24/179 (13.4)	18.5	8.7, 28.3
Difficulty getting up in the morning	34/120 (28.3)	26/178 (14.6)	13.7	4.1, 23.4
Thoughts of others harming you	34/120 (28.3)	27/180 (15.0)	13.3	3.7, 23.0
Thoughts of harming other people	37/120 (30.8)	26/180 (14.4)	16.4	6.6, 26.1

between suicide attempters and nonattempters, alcoholic or controls.

Discussion

The results suggest that it may not be youthfulness per se which is critical in the relatively high percentage of young female suicide attempters seen in hospital emergency rooms but the combination of youth and substance abuse. Among the nonalcoholic women in this study, there was little difference in the proportion of suicide attempters among younger and older women.

An attempt was made to deal with the question of bias in the selection of clinical subjects by interviewing the patients of 21 different treatment facilities. While the facilities were limited to southeastern Michigan, they represented a wide range of treatment orientations and methods. One may question whether alcoholic and control women are equally likely to admit to a suicide attempt, to remember such an attempt, or to report a suicide attempt. There is no unequivocal answer to this question, but if experimental procedures are reasonably well planned, and the interviewers skilled so as to establish excellent rapport, one can assume that the groups of women were reasonably comparable on this score.

Why the age differential among alcoholic women? One could speculate about the role of depression, impulsivity, hostility, hysterical trends, risk-taking behaviors, and combinations thereof—and the linkage between such patterns of behavior and heavy alcohol intake among different age groups of alcoholic women. Analyses of other data obtained in this study of alcoholic women[21] show nonsignificant age differences in depression among alcoholic women, but significant age differences in early history of impulse control.[23]

Emergency room personnel are acutely aware of the problems of drug overdose and drug abuse. It is worth reiterating: while it is true that young women are a high-risk group for suicide attempts,[24] it is also true that such attempters are likely to have a history of alcohol or other drug abuse. Whether this is due to "... social stigmatization and disapprobation"[25] is beside the point. A person presenting with a suicide attempt is in need of assessment and appropriate referral from the emergency room. As for substance abuse treatment facilities, it is important that they be aware of the suicide attempt potential of young women drug abusers; the abuse of a given substance or substances may not be preventable at the point of entry into treatment but suicide attempts should be investigated with the goal of prevention of such attempts.

Prevention '90 Set for April 18–22, 1990 in Atlanta

"Assuring the Public's Health" will be the overall theme of the Prevention 90 meeting, to be held April 18–22, 1990 in Atlanta. This will be the 7th annual national meeting on disease prevention and health promotion sponsored by the American College of Preventive Medicine, the Association of Teachers of Preventive Medicine, and co-sponsored by a number of other health organizations, including the American Public Health Association.

To receive further information and obtain the standard abstract forms, contact: Joanne Angle, Association of Teachers of Preventive Medicine, 1030 15th Street, NW, Suite 410, Washington, DC 20005. Telephone: (202) 789-2928.

The deadline for abstract submission is October 6.

Business Recession, Alcohol Consumption, Drinking and Driving Laws: Impact on Oklahoma Motor Vehicle Fatalities and Fatal Crashes

ANDREAS MULLER, PHD

Abstract: In 1982, Oklahoma enacted a series of drinking and driving laws. In the ensuing years, motor vehicle fatalities and fatal crashes were reduced by one-third. Factors contributing to this reduction were examined using interrupted time series analysis of monthly rates of motor vehicle deaths and fatal crashes for the period January 1980 to December 1986. Decreasing per capita alcohol consumption and increased unemployment apparently account for most of the fatality and fatal crash reduction in Oklahoma. The enactment of two traffic safety laws—one specifying the illegal blood alcohol concentration level (BAC law) and the other facilitating license withdrawal from suspected drunk drivers (administrative per se law)—together reduced Oklahoma traffic deaths and fatal crashes by about 9 percent. The effectiveness of the laws appeared to be greatest in the first two years following their enactment. (*Am J Public Health* 1989; 79:1366–1370.)

Introduction

In 1983, Oklahoma motor vehicle fatalities decreased by more than one-fifth and have continued to decrease since then.[1] The oil shortage and the reduction of the national speed limit in 1973 had less impact on motor vehicle fatalities. The only comparable decrease in such deaths occurred in 1942, reflecting the American entry into World War II.

In July 1982, the Oklahoma state legislature established a blood alcohol concentration level of .1 g/dl (22 mmol/L) as "evidence per se" of driving while intoxicated (BAC law). In April 1983, this law was reinforced by an administrative per se law (ADM law) permitting automatic license revocation, if a police officer was refused the right to administer a blood alcohol test to a suspected drunk driver. In September of the same year, Oklahoma raised the minimum age for purchase, possession, and consumption of beverages in excess of 3.2 percent alcohol concentration from 18 to 21 years.[2] An interrupted time series analysis of monthly motor vehicle fatalities and fatal crashes from January 1975 to March 1986 suggested that the law reduced Oklahoma fatalities and fatal crashes by about one-third.[3] In addition, the effectiveness of the administrative per se law appeared to increase over time; this finding departed from previous studies showing the deterrent effect of drunken-driving laws and related enforcement campaigns to be short-lived, reviewed elsewhere.[4]

The findings of an effect of the Oklahoma laws contrast with studies of similar legislation enacted in California, Maine, and Massachusetts conducted by Hilton[5] and Hingson, *et al*,[6] which have found the trends in monthly single-vehicle night time fatal crashes comparable to those in adjacent states without the legislation and to trends in non-alcohol-related fatal crashes.

A recent nationwide study by the Insurance Institute for Highway Safety (IIHS) for the period 1978–85 found that administrative per se laws and BAC laws reduced fatal crashes by 4.6 percent and 2.4 percent, respectively. State-specific variation in effectiveness may occur and can only be determined by additional analyses.

Unlike other parts of the United States, Oklahoma experienced an oil-related economic boon during the period 1980–82 followed by a severe recession beginning with Penn-Square Bank failure in July 1982. The recession was prolonged by a sharp drop in crude oil prices in January 1986. The unemployment rate for the civilian labor force in Oklahoma increased from a 4–5 percent level in 1980–81 to over 10 percent in early 1983, receded to 7–8 percent in 1984–85, and increased again in 1986 (Figure 1). Business conditions affect the motor vehicle fatality trend since unemployment reduces work-related travel and disposable income, making alcohol consumption and leisure travel less likely.[8]

Apart from the effects of business cycles, alcohol consumption patterns have changed over recent years, with decreased consumption of distilled liquor and increased consumption of beer and wine having the overall effect of reducing the per capita amount of pure alcohol (ethanol) consumption since 1982.[9] Correspondingly, between 1982 and 1986, the proportion of fatal crashes involving intoxicated drivers has decreased by 11 percent.[10] Per capita pure alcohol consumption by Oklahomans (Figure 2) parallels the national trend showing a gradually decreasing trend since 1982.

Since alcohol consumption contributes to motor vehicle crashes and deaths, the gradual reduction in alcohol consumption in Oklahoma should have resulted in fewer alcohol-related crashes regardless of the imposition of stricter alcohol-related traffic safety laws. The effect of such legislation would be overestimated if the alcohol consumption trend and the effect of the business recession were not controlled.

Methods

The time series analysis was based on three sets of data pertaining to motor vehicle fatalities and fatal crashes for the period January 1980 to December 1986 (n = 84). The first data set included all deaths whose cause was coded E810-E825, ICDA-9 for Oklahoma residents.[11] About 3 percent of the fatalities occurred beyond state boundaries.

The second data set pertains to the number of crashes involving at least one fatally injured person. Fatal crashes involving heavy trucks and buses (7 percent) were deleted, since operators of those vehicles are likely to be out-of-state residents unfamiliar with Oklahoma's laws regarding drinking and driving.

The third data set is a subset of the second, removing fatal crashes involving drivers under 21 years of age. This deletion controls for the potentially confounding effect of the change in the minimum drinking age law. Due to the small number of fatal crashes involving persons under 21 years of age, no reliable analysis of the effect of the minimum drinking age law could be performed.

To control for changes in Oklahoma's population, we divided the time series by the appropriate population estimates.[12] The time series of fatal crashes involving drivers over 20 years of age was divided by the corresponding age-specific population estimates; the two remaining series were divided by estimates of the total population. The procedure resulted in three sets of rates:

- monthly motor vehicle deaths per 100,000 population,
- monthly fatal crashes per 100,000 population, and
- monthly fatal crashes involving adult drivers per 100,000 population over 20 years of age.

The data pertaining to fatal crashes were extracted from Department of Transportation files and provided by staff of the Oklahoma Highway Safety Office. The unemployment data including estimates for 1986 were obtained from staff of the Oklahoma Employment Security Division.

The Oklahoma Department of Public Safety released license revocation data pertaining to BAC testing. Inspection of the time series and discussion with the administrator of the records division showed that reporting lags of one to two months occurred occasionally. To even out such lags, the data were averaged by quarter.

Oklahoma per capita alcohol consumption was estimated from data provided by the alcoholic beverage industry (Appendix A). The time series were analyzed by ordinary least squares multiple regression using SPSS-X Trends computer software[13] (Appendix B).

Results

Monthly time series of motor vehicle death rates and fatal crash rates in Oklahoma (Figures 3, 4) showed typical seasonality with the highest rates in the summer months and the lowest rates in February. The time series for the subgroup of fatal crashes with adult drivers (not shown) was very similar to those shown. All time series have one exceptionally high rate, August 1982, an outlier removed in subsequent analyses (see Appendix B). The trend began to decrease late in 1982, reached a new plateau by the last quarter of 1983, and decreased more slowly thereafter.

Table 1 shows the best fitting regression models using dummy variables and counters for the three monthly time series. The models indicate that with the enactment of the BAC law (July 1982) the level of the time series dropped between 5.9 and 12.2 percent. With the enactment of the administrative per se law (April 1983), the levels of the time series further dropped between 9.7 and 13.2 percent when compared with levels before the enactment of the law. n = 84

negative coefficients for the ADM time counter indicate that the rates continued to decrease. By December 1986, the fatality and fatal crash rates were about one-third lower than before the enactment of the laws.

Table 2 shows the decrease in motor vehicle deaths and fatal crashes associated with increased unemployment, reduced alcohol consumption, and the administrative per se law. Depending upon the time series, the law appeared to have reduced fatality and fatal crash rates between 7.1 and 10.6 percent. However, the coefficients for the BAC law were inconsistent in sign and statistically insignificant. Therefore, the BAC law dummy variable was deleted from the final mode specification.

Another analysis, shown in Table 3, includes fatal crashes in Oklahoma which police determined not to be alcohol related. This series is a proxy for changes in extraneous factors, such as travel or weather. In addition, the dummy variables and counters representing BAC and administrative per se laws are replaced by a measure of enforcement of drunken driving: the number of licenses revoked involving BAC tests.

The models fit the time series very well, mainly because the series is regressed on the time series of nonalcohol-related fatal crashes. The multiple regression estimates show that per capita alcohol consumption increases fatality and fatal crash rates, while increased law enforcement has the opposite effect. Increased enforcement reduced motor vehicle death rates by 9.6 percent after the enactment of the administrative per se law, and by 5.0 percent during the nine-month period (7/82 to 3/83) during which only the BAC law was in effect. The estimates are similar for the time series of fatal crash rates.

In Table 3 the unemployment rate showed a weak direct effect, because part of the overall unemployment effect was shared by the trend of nonalcohol-related crashes.

Police enforcement varied over the study period (Figure 5), with a gradual increase in license revocations following enactment of the BAC law. Enforcement was highest during the first quarter after the enactment of the administrative per se law. Thereafter, enforcement activity declined until early 1985 despite some seasonal variation. Thus, the effect of the two laws should have been most pronounced during the first year after enactment of the administrative per se law. It is estimated that fatal crash rates of adult drivers were reduced by 12.3 percent during the first year of enactment of the administrative per se law, 10.8 percent during the second year of enactment, and 7.8 percent during the remaining 21 months (4/85–12/86). Since both laws were in effect from April 1983 on, the estimates reflect the combined effective-

ness of the laws. The effectiveness of the BAC law for the nine-month period preceding the introduction of the administrative per se law is estimated at about 5 percent.

Discussion

The enactment of a BAC law and an administrative per se law in Oklahoma reduced fatality rates and fatal crash rates by about 9 percent in the four years following their enactment. This estimate is less than one-third of the size found in a previous study of the effectiveness of the Oklahoma administrative per se law.[3] The difference in estimates is due mainly to the control of alcohol and to unemployment trends which were not considered in the earlier study.

The effect of the BAC law was not statistically significant when other variables were controlled and deleted from the analysis (Table 2). The most plausible reason is that the enactment of the BAC law nearly coincided with rapidly rising unemployment making the BAC regression estimate unreliable. However, when license revocations were used to determine the effectiveness of the laws, the BAC law was estimated to have reduced fatality and fatal crash rates by about 5 percent. This estimate pertains to the initial nine-month period separating the two laws; the long-term effectiveness of this legislation may be different. A recent nationwide study estimated an average (long-term) effect of 2.4 percent for BAC laws and 4.6 percent for administrative per se laws.[7] These estimates approximate the combined long-term effect (7.2 percent), past two years, found in this study.

Deleting fatal crashes involving drivers under 21 years of age did not markedly affect the estimated effectiveness of the laws (Table 3). This finding suggests that the BAC and the administrative per se law are responsible for the decrease in fatal crash rates rather than the raising of the minimum drinking age law.

The accuracy of police-reported alcohol-impaired driving is a concern in this study. Oklahoma police could not determine alcohol involvement for 11 percent of drivers involved in fatal crashes. The percentage was about the same from 1980 to 1986 suggesting no increased effort by police to report alcohol involvement in fatal crashes.

In addition, an increase in the reporting of nonalcohol-related fatal crashes coinciding with the enactment of the laws could not be found. Such a change would be expected, if police officers became more lenient when faced with administering harsher legal sanctions. Errors in the reporting of alcohol involvement would not bias the regression estimates unless the error rate changed over time; no evidence supporting this conclusion could be found.

The gradual reduction in per capita alcohol consumption has had a substantial effect on Oklahoma's fatal crash trend. The annual per capita consumption dropped by about .4 gallons pure alcohol between 1981 and 1986. The corresponding decrease in motor vehicle death and fatal crash rates is estimated at 12–14 percent, controlling for changes in unemployment and drinking and driving laws.

The total effect of the business recession, measured by the unemployment rate, is less clear. Since the unemployment rate was on the average 4 percent higher after the enactment of the drinking and driving laws, about 10 percent of the reduction in death rates should be due to increased unemployment.

However, increased unemployment appears to have had little direct effect on fatal crash rates, although indirect effects via the other variables are consistent with the findings. For instance, unemployment had a significant negative effect on nonalcohol-related fatal crashes. A 4 percent increase in the unemployment rate reduced fatal crashes by 2/100,000 controlling for seasonal variations. Thus, increased unemployment, by reducing nonalcohol-related fatal crashes, could have contributed to a 7 percent reduction in the fatal crash rates.

APPENDIX A

Per Capita Alcohol Consumption Index

Data for estimating monthly per capita consumption of pure alcohol (ethanol) in Oklahoma are provided by the Distilled Spirits Council of the United States, the Beer Institute and the Wine Institute. The data pertain to shipment and sales records regularly compiled by the alcoholic beverage industry. Beer and wine data were provided by month, while distilled spirits data could only be obtained by year. To estimate monthly pure alcohol consumption, the data were converted into gallons and the annual amount of distilled spirits was divided by 12. The following formula was used to derive the estimated monthly per capita alcohol consumption.

P.C. ethanol consumption = (.414 * DSP + .033 * Beer + .129 * Wine) * 12/POP;(1)

where: DSP = distilled spirits (gl.);
POP = Oklahoma resident population over age 20;

The coefficients for distilled spirits and wine refer to the average alcohol concentration estimated by the Alcohol Epidemiological Data System.[14] The average alcohol concentration of beer is less in Oklahoma than in other states,

due to the mandated 3.2 percent limit for beer sold in grocery and convenience stores. According to Oklahoma tax receipt data, only 5 percent of beer has higher alcohol concentration. The estimated average alcohol concentration of beer sold in Oklahoma is estimated to be 3.3 percent.

APPENDIX B

Statistical Model and Method of Analysis

The time series are analyzed by a form of multiple regression which uses dummy variables and dummy counters to represent changes in the level (mean) and trend (slope) of the time series.[15,16] Another set of dummy variables is used to represent seasonality.[17] The basic model for this study is as follows:

$$Y_t = a + b_1X_1 + B_2X_2 + B_3X_3 + B_4X_4 + \Sigma B_iX_i + e_t; \quad (2)$$

where: Y_t = monthly motor vehicle death rate (fatal crash rate);
a = reference category;
b_i = regression coefficients;
X_1 = linear trend counter, coded 1 to 84;
X_2 = dummy variable, coded '0' before BAC law went into effect and '1' thereafter;
X_3 = dummy variable, coded '0' before administrative per se law went into effect and '1' thereafter;
X_4 = dummy variable counter, coded '0' before administrative per se law went into effect and '1' to n thereafter'
ΣX_i = set of 11 dummy variables identifying months (January to November) representing seasonality;
e_t = error term;

The set of monthly dummy variables controls for seasonal fluctuations in the time series, while the linear trend counter X_1 controls for any existing secular, linear trend which is independent of the effects of traffic safety laws. The effects of the two laws are modeled by variables X_2 to X_4. The laws may be effective, if one or more of the coefficients associated with variables X_2 to X_4 are negative and statistically significant. To prevent multicollinearity, a dummy variable counter for the BAC law was excluded from the model.

In order to control for unemployment and alcohol consumption trends, these variables were added to equation (2). The best-fitting model was determined by deleting statistically insignificant terms and by inspecting residual plots.

First, extreme outliers ($z = \pm 2.57$ standard deviations) were replaced by linear interpolation using data pertaining to adjacent months. Data for August 1982 and March 1984 (observations 32 and 51) were replaced by this method normalizing the distributions of residual plots.

Second, the distribution of residuals for the best-fitting models did not significantly depart from homoscedasticity, although the variances of residuals were somewhat smaller for the period after the laws went into effect. Converting the dependent variables to their natural logarithms further stabilized the variance of residuals, but did not change the regression estimates substantially. The time series were also analyzed by weighted least squares regression without substantial change in findings.

Third, besides Durbin-Watson tests of the first order autocorrelation, the residuals were tested by the Box-Ljung statistic. The latter tests showed that higher order autocorrelations were small and consistent with a random process. The autocorrelation plots indicated no significant spikes at critical lags for models including the control variables.

ACKNOWLEDGMENTS

I would like to thank Rae Ann McMahon, Brett Tyhurst, Tracy Coulter for their competent research assistance and Randy Jorgensen (OHSO), Delbert Karnes (OHSO), Roger Jacks (Oklahoma Employment Security Commission), Lynne Strang (Distilled Spirits Council of the U.S.), Jeff Millefoglie (Wine Institute) for supplying pertinent data and publications.

6th National Cancer Communications Conference Set for January 1990

The National Cancer Institute and the American Cancer Society are co-sponsoring the Sixth National Cancer Communications Conference, January 10–12, 1990, in Washington, D.C. The theme of the conference is "Toward the Year 2000: Promoting Cancer Control through Communications."

Experts from around the world will address the emerging issues affecting communications as a factor in cancer control. More than 30 workshops, seminars, and training sessions on education, media, public and patient education, and public policy.

For more information, contact the Sixth National Cancer Communication Conference, 1801 Rockville Pike, Suite 500, Rockville, MD, 20852 or call (301) 468-6338.

Six-Year Follow-up of the First Waterloo School Smoking Prevention Trial

BRIAN R. FLAY, DPHIL, DAVID KOEPKE, PHD, SHIRLEY J. THOMSON, MA, SUSANNE SANTI, MSC, J. ALLAN BEST, PHD, AND K. STEPHEN BROWN, PHD

Abstract: This paper reports six-year follow-up data from the first large-scale randomized trial of the social influences approach to smoking prevention. In 1979, 22 schools were randomly assigned to program or control conditions. Students in program schools received a social influences curriculum in six core and two maintenance sessions in grade 6, two booster sessions in grade 7, and one booster session in grade 8. All students were assessed at pretest (T1), immediate posttest (T2), end of grade 6 (T3), beginning and end of grade 7 (T4 and T5), end of grade 8 (T6), and grades 11 and 12 (T7 and T8). Ninety percent of study students were relocated and data obtained from over 80 percent of them at T8. Program effects on experimental smoking observed in grades 7 and 8 had completely decayed by T8, six years after the beginning of the program. Grade 6 smoking experience and social risk were each strong predictors of T8 smoking behavior. Subjects who had left school were smoking at more than twice the rate of subjects still in high school (grade 12) at T8. We discuss implications of the results. (*Am J Public Health* 1989; 79:1371–1376.)

Introduction

The social influences approach to smoking prevention has proven efficacious in a large number of studies.[1,2] The approach concentrates on making students aware of the social pressures to smoke—from peers, parents and other adults, and the mass media—and on teaching them behavioral skills with which to resist such pressures. Most studies have reported about 50 percent reduced levels of smoking onset by students exposed to social influences programs when compared to control students, at least in the short term. Ultimately, however, the effectiveness of the tested programs, and of the social influences approach generally, must be assessed from long-term results. We must be able to reduce the prevalence of smoking in high school and beyond.[3]

Long-term Effects

To date, only a few investigators have reported results of social influence interventions into high school or beyond two years after the intervention (Appendix A).[4–10] Reported effects become smaller at longer follow-ups, until they disappear altogether at six-year follow-up.[10] Results in all cases are difficult to interpret because of alternative methodological explanations.[1,2] These methodological problems were overcome in "third generation" studies,[1,2] of which the Waterloo study was one. The data reported here are the first long-term follow-up data to be reported from a "third generation" study.

The Waterloo Study

The first large-scale randomized trial of the social influences approach to smoking prevention was initiated in Waterloo, Canada in 1979. At that time, 22 schools with grade 6 students were randomly assigned to receive or not receive a social influences curriculum. Grade 6 students in the 11 program schools received a 6-session curriculum from research staff. Two maintainence sessions were provided at the end of grade 6, two booster sessions in grade 7, and one booster session in grade 8. Appendix B provides a summary of curriculum content, and further details are provided in previous publications.[11–13]

Students in both program and control schools were assessed by questionnaire at pretest (T1), immediately after the core program (T2), at the end of grade 6 (T3), at the beginning and end of grade 7 (T4 and T5), and at the end of grade 8 (T6). Potential underreporting of self-reported smoking behavior was minimized by assurances of confidentiality, and collection of a sample of saliva as a modified "bogus pipeline."[14] Results indicated that although the program did not reduce levels of regular smoking or significantly increase the probability of remaining a nonsmoker, it was successful at preventing the onset of experimental smoking up to the end of grade 8.[12,13] Results were especially encouraging for high-risk students—those at risk to become smokers because they had already tried smoking at grade 6 or because their parents, siblings, and friends were smokers.[11]

Methods

Subjects

Participants in the first Waterloo smoking prevention trial were reassessed five and six years after the beginning of the study, in grades 11 (T7) and 12 (T8). Extensive tracking procedures resulted in the location of a large percentage of the original subjects. For the 11th grade (T7) assessment, 79 percent (223) of the original 281 subjects from one school board were located and 68 percent were tested. However, failure to obtain cooperation from one school board in time resulted in a failure to assess many subjects in grade 11, and only 40 percent (166) of the 412 subjects from the second school board were located, and 35 percent (143) tested. Overall 56 percent (389) of the subjects were located and 48 percent (335) tested.

The following year we obtained increased cooperation from the second school board. This enabled us to locate 623 (90 percent) of all study students and to obtain questionnaire data from 532 (77 percent) of them and telephone information from an additional 28 (4 percent). Therefore, all outcome results reported below are limited to data from T8 when we obtained responses from most subjects.

Measures

Measures used at T8 were essentially the same as those previously used in grades 6 through 8. In addition to self-reported smoking behavior, students and school leavers were asked for demographic information; reports of smoking habits of parents, siblings, and friends; and information on a

set of mediating variables including knowledge and beliefs regarding smoking, environmental change (from grade school to high school), other substance use, and academic aspirations. Students were also asked for reports of smoking habits of teachers, and information on school environment (including smoking regulations and enforcement).

Smoking behavior categories—On the basis of self-reported smoking behavior, subjects were classified as being in one of five behavioral categories at pretest and at the 12th grade follow-up:

- Never smoker (never smoked even one puff of cigarette);
- Tried once (has smoked, but only once);
- Quitter (has smoked more than once, but has "quit for good");
- Experimenter (currently smokes, but less than once a week);
- Regular (currently smokes at least once a week or more).

Some analyses reported below compare regular smokers against all others. For some analyses, we also classified subjects as to whether or not they were currently smoking at all.

Pretest social environment risk—Risk levels were based on pretest responses to questions about the smoking habits of parents, siblings, and friends. Levels were defined as follows:

- Low risk (no smoking parents, siblings, or friends);
- Intermediate risk (smokers in only one of the three social model groups);
- High risk (smokers in two or all three social model groups).

Both the behavior smoking category and the social environment classifications depend on multiple questionnaire responses. If needed items were missing, the subjects were unclassifiable and excluded from the analyses. Over 93.5 percent had smoking behavioral categories for both pretest and 12th grade and 91 percent had complete data for all variables used in the analysis.

Procedure

Most subjects were still in school, and in the high schools they expected to be in when they last participated in the study. However, a significant number had changed schools or dropped out. Extensive tracking procedures were initiated to find and assess as many of these students as possible. Those students who had left school or had moved to another area were surveyed by mail (see reference 15 for details).

Those students located in schools in the vicinity of the University of Waterloo were surveyed in classrooms. Participation in measurement was by full informed consent by both the students and their parents. Confidential ID numbers enabled us to match student responses across waves of data collection.

Results

Attrition Analyses

Measures taken at T1 were used in a logistic model[16,17] to determine whether subjects lost at T8 differed systematically from those who were retained. Effects analyses could be biased to the extent that variables related to outcome behavior also relate to the process of attrition. There was no significant relation between treatment condition and attrition. Neither was there a relation between pretest social environment risk and attrition. However, there was a relation between pretest smoking behavioral category and attrition, with greater attrition of pretest triers compared to never smokers (odds ratio = 1.84, 95% CI = 1.04, 3.28). Age was also related to attrition. The study retained more subjects who were ages 9–11 at pretest compared to those who were age 12 or older (OR = 2.53, 95% CI = 1.45, 4.39). (These older subjects were more likely to have left school and were thus more difficult to track.) As both students smoking at pretest and older students were more likely to be smoking at the time of the follow-up, these differences tend to bias downward observed smoking rates across all conditions.

Smoking Levels

Approximately 33 percent of all subjects at T8 were regular smokers (95% CI = 27.95, 38.72) and another 10 percent were experimental smokers (95% CI = 6.63, 13.49). By this time only 15 percent had never tried a cigarette (95% CI = 11.07, 19.26).

Students and school leavers—Students and school leavers reported very different patterns of smoking behavior. Approximately 68 percent of school leavers were regular smokers compared to 28 percent of students still in school at grade 12 (OR = 5.54, 95% CI = 3.14, 9.79). Nearly all of the school leavers (98 percent) reported having tried smoking compared to only 84 percent of the students (OR = 12.50, 95% CI = 1.71, 91.8). Figure 1 presents smoking behavioral categories for students in grade 12 and for school leavers.

Measures taken at T1 were used in a logistic model to predict school leaving six years later at T8. There were no significant differences between students and school leavers by original school board, treatment condition, or pretest social environment risk. There were, however, differences by age and by pretest behavioral smoking category. Most of the students were 11 years old at the time of the intervention, but a few were as young as 9 years or as old as 14. Students who were age 12 or older at the time of the pretest were more likely to have left school than those who had been ages 9–11 (OR = 5.05, 95% CI = 2.53, 10.08). Those who had tried smoking once at the time of the pretest were more likely to leave school than those who had never smoked (OR = 2.95, 95% CI = 1.38, 6.29), as were those who had quit (OR = 3.21, 95% CI = 1.30, 7.91) and those who had been regular smokers at the pretest (OR = 7.49, 95% CI = 2.15, 26.09).

However, age and pretest smoking rate differences cannot account for all differences between smoking rates of students and school leavers at the T8 follow-up. When age,

Treatment Condition		
Treatment vs Control	1.24	(0.83, 1.86)

pretest behavioral smoking category, social environment risk, original school board and treatment condition are included with school leaving in a logistic model to predict regular smoking at T8, there is still more regular smoking by school leavers than by students (OR = 2.18, 95% CI = 1.58, 3.01).

Program Effects

Overall program effects also were assessed using a multiple logistic model. The dependent variable is smoking at T8. The primary predictor is treatment condition. The model includes smoking behavioral category at the 6th grade pretest (T1) and pretest social environment risk as additional predictors. These were previously shown to be effective predictors of smoking at the end of 8th grade (T6).[11,13] Original school board is included as a blocking factor for possible differences between the two populations. Table 1 summarizes the results of this analysis. Interactions of treatment condition with each of these two variables then were added to assess possible differential program effects for students at differing degrees of risk. These interactions were not significant.

By T8 there is no longer a significant overall effect for the treatment program. Both pretest social environment risk ($p < .05$) and pretest smoking behavior ($p < .0001$) predict whether students are smoking more than six years later. The odds ratio indicate that those at low social environment risk in grade 6 are least likely to be smoking six years later. There is no significant difference in smoking rates between the two original school districts. Since the interactions are insignificant, there do not appear to be any differential effects of the treatment program for students at different initial levels of risk for smoking. The overall likelihood-ratio test (*Chi-square* = 30.86, $df = 38$, $p > .75$) indicates that the terms in the model are adequate to account for the observed patterns of responses.

A parallel analysis was done using regular smoking as the outcome measure. Table 2 summarizes these results. A similar pattern of effects is observed for regular smoking (at least once a week) as for smoking at all. There are no overall program effects nor differential program effects for students at differing initial levels of risk. Pretest smoking behavior category ($p < .0001$) predicts whether a student is a regular smoker at T8. Pretest social environment risk is a less strong predictor ($.05 < p < .10$) but the odds ratio are in the same direction for regular smoking as they were for smoking. The likelihood-ratio test (*Chi-square* = 43.42, $df = 38$, $p > .25$) indicates that the terms in the model are adequate to account for the observed patterns of responses.

Thus, six years after the beginning of the intervention, there were no overall differences between the program and control groups when all students are considered together. Figure 2 displays the proportion of subjects smoking regularly and experimentally at each wave by experimental condition. It demonstrates decay of the significant difference between conditions in level of experimental smoking that was observed at grades 7 and 8.[13]

Considering pretest smoking behavior and social risk categories,[11] Figures 3 and 4 show how pretest risk is a strong predictor of subsequent smoking level. The probability of regular smoking in high school increases as grade 6 risk increases; the probability of experimental smoking in high school is lowest for the students at lowest risk in grade 6, and the probability of never smoking by grade 12 decreases as grade 6 risk increases. At grades 7 and 8, we observed significant program effects for the high- and middle-risk students—we did not observe effects for the low-risk students because only a few of them had tried smoking by grades 7 and 8. We observed no significant differential program effects by 12th grade for any risk group.

Discussion

Observed effects of the Waterloo program on the onset

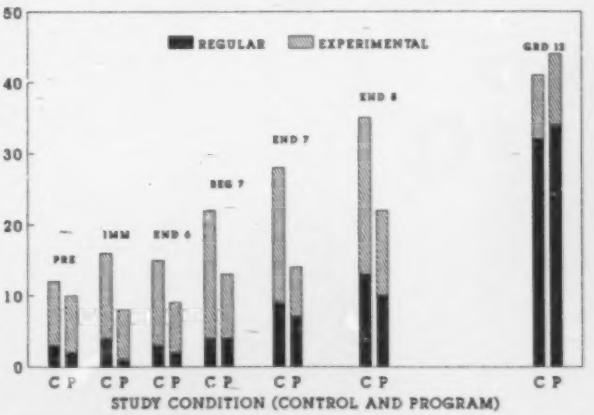

FIGURE 2—Proportion of Subjects Smoking Regularly and Experimentally at Each Wave of the Study

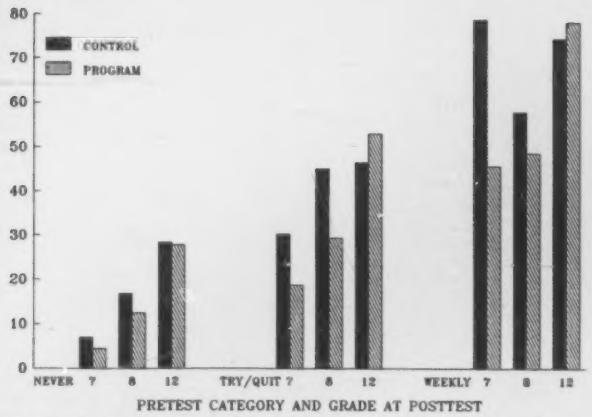

FIGURE 3—Percentage of T8 Subjects Smoking by Pretest Smoking Category and Experimental Condition

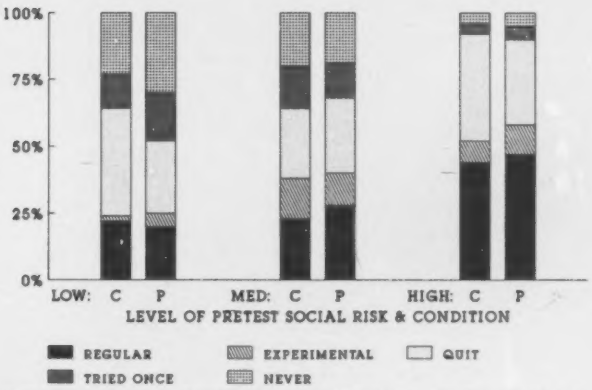

FIGURE 4—Percentage of T8 Subjects in Each Behavioral Category by Pretest Social Risk Level and Experimental Condition

of experimental smoking in grades 7 and 8 were not maintained through grade 12. Expected effects on grade 12 smoking (regular or experimental) did not occur. This finding is consistent with that of the only other study of long-term effects of adolescent smoking prevention programs.[9,10]

The lack of significant preventive effects by grade 12 raises the question of the value of the social influences approach for smoking prevention. In retrospective non-intervention studies, delayed onset is associated with improved prognosis for quitting and lower incidence of total morbidity and mortality.[18,19] Prevention program-induced delays in onset may reduce total lifetime exposure and may be an important outcome.[10] This is particularly true if delayed onset increases the probability of earlier quitting. However, the extent to which an intervention-induced delay in onset is associated with earlier or more successful quitting, or even with decreased exposure to toxins, is not established. That would require following the subjects of this study, and others like it, into middle adulthood. We might expect to find earlier quitting by subjects who are currently smokers but who delayed onset until grade 9 or 10, partly because of the delayed onset and partly because of reduced peer influences.

The value of the social influences approach to preventing the onset of regular smoking by the end of high school needs further study. Results from both the Minnesota and Waterloo studies suggest that program effects obtained in junior high school decay gradually during the following years to totally disappear by grade 12. Such a pattern suggests that booster sessions might be necessary. However, the Waterloo results suggests that boosters in grade 8 are insufficient. These results, together with findings of increased risk at the transition from one level of school to another[20] (or from school to college or working), and the importance of school policy variables[21] suggest the need for boosters in high school. Results of reported high school interventions[6,22,23] suggest that social influence curricula can be effective with high school students, although effects were small in all cases. Booster sessions were also recommended by an expert advisory panel convened recently by the National Cancer Institute.[24]

The apparent lack of effects of social influence programs on smoking prevention by grade 12 should not be over-interpreted. First, as noted above, boosters in early high school years may help to maintain early substantial effects. Second, there is a much better understanding today than 10 years ago of the essential components of effective prevention programs.[24] These improvements may well mean that current versions of social influence programs may produce more durable effects. Third, the broader social norms are now more supportive of nonsmoking, so that students in control schools may, in fact, have been exposed to many of the elements of the social influence approach during the last five years.

One alarming result of this study is the large difference in smoking behaviors between students and school leavers. These differences cannot be explained by differences in age or by pretest differences in smoking risk or experience, and they also replicate results from the Minnesota group.[25] Indeed, they may be underestimated in both the Minnesota and this study because school leavers were followed up less successfully than subjects still in school. The high rates of smoking by early school leavers or dropouts warrant special attention by future research. Prevention programs for youth who will leave or drop out of school will need to go beyond the school setting. Early cessation programs also need to be developed for this group, and these will require components designed to motivate young adults to consider quitting, something which most current smoking cessation programs do not include.

Additional studies of the long-term effects of social influence prevention interventions are necessary. We cannot draw strong inferences from only the two long-term follow-up studies conducted to date. The short-term effects of the social influences approach appeared very promising, but interpretation of their long-term value must await further long-term follow-up studies.

APPENDIX A

Results and Characteristics of Long-term or High School Follow-up Studies on Smoking Prevention

Authors/ Date/Reference	Length of Follow-up (Years)	School Grade of Program	Program Effect (Yes or No)	Methodological Problems (See below)
Evans, *et al*, 1981[4]	3	7	Y	a,b
Telch, *et al*, 1982[5]	2	7	Y	c,d
Johnson, *et al*, 1986[6]	1	10	Y	a,e
Hansen, *et al*, 1988[7]	3	7	Y	a,e
Luepker, *et al*, 1983[8]	2	7	Y	f
Murray, *et al*, 1988[9]	4–5	7	Y	f
Murray, *et al*, in press[10]	5–6	7	N	f

Methodological problems:
a) Serious attrition.
b) Reliance on successive cross-sectional analyses of different subjects.
c) Pretest differences.
d) Unable to follow same subjects over time.
e) Marginal significance.
f) Pretest differences in direction of expected effects.

APPENDIX B

Summary of Content of the First Waterloo Smoking Prevention Program

Session	Components	Purpose	Methods
Core program (Six one-hour sessions)	Informational	Provide factual basis for the rest of the program.	Film Classroom discussion Poster-making Videotapes Categorization
	Skills Development	Develop and practice skills to resist social influences to smoke.	Videotapes Modeling Role playing Poster-making
	Decision-making	Integrate other components and express intentions.	Decision sheet Public commitment to class
Maintenance (same grade)		Reestablish contact Review	Poster-making Classroom discussion "Talking" videotape Categorization
Booster sessions (grades 7 & 8)		Reestablish contact Review Update information and skills	Classroom discussion Small group work Decision sheet Role playing

RWJ Foundation Extends Grants Program for Native American Health Projects

The Robert Wood Johnson Foundation recently awarded nearly $2 million to fund 13 community health care projects run by and for American Indians and Alaska Natives, and in a further commitment has allocated additional funds to extend the program through 1990.

Believed to represent the first commitment by a major foundation to work directly with tribal governments, the 1989 grants program will target projects designed to prevent alcohol and drug abuse, control diabetes, reduce domestic violence, and improve maternal and infant health among tribal populations in eight states (AZ, ID, MN, MT, NM, OK, SD, and WI). The tribes plan to approach their health problems with imagination and creativity, using traditional Indian methods of care as well as modern medical technology, according to the foundation.

When the call for proposals was issued last fall for the program, "Improving the Health of Native Americans," the foundation received applications from Indian-related groups in 31 states. The high quality and magnitude of that response prompted the foundation to commit additional funds of up to $2 million to continue the program in 1990.

Tribes and related community organizations interested in applying for funds under the program's second phase should contact Timothy L. Taylor, PhD, Program Director, Improving the Health of Native Americans, College of Public Health, University of Oklahoma Health Sciences Center, PO Box 26901, Oklahoma City, OK 73190. Tel: (405) 271-3221. Dr. Taylor is also a member of the Kiowa Tribe.

Two workshops for potential applicants will be held in November in Nashville, TN and Denver, CO, to answer questions about the program and the application process. For more information about the workshops, contact Dr. Taylor at the address above.

Grants under the program's second phase will be announced in August 1990; proposals must be received by February 1, 1990 to be considered for funding.

The RWJ Foundation, based in Princeton, NJ, is the nation's largest health care philanthropy, established in 1972. Since then, it has awarded more than $996 million in grants to improve health care in the United States.

Elevated Blood Levels of Carcinogens in Passive Smokers

MALCOLM MACLURE, ScD, RONIT BEN-ABRAHAM KATZ, MD, MATTHEW S. BRYANT, PhD, PAUL L. SKIPPER, PhD, AND STEVEN R. TANNENBAUM, PhD

Abstract: The hypothesis that involuntary exposure to tobacco smoke—passive smoking—results in greater risk of cancer was assessed by measuring the levels of two known carcinogens in the blood of 57 nonsmokers with varying degrees of involuntary exposure, including six heavily exposed bartenders. The concentrations of hemoglobin adducts of 4-aminobiphenyl, a bladder carcinogen, were significantly higher in subjects with confirmed involuntary exposure (plasma cotinine concentrations between 2 and 23 ng/ml) compared with subjects with undetectable levels of cotinine. Similarly, adducts of 3-aminobiphenyl were significantly elevated in subjects with confirmed exposure. The odds of 3-aminobiphenyl adduct levels exceeding 2 pg/g of hemoglobin were 6:7 among the confirmed exposed, compared with the odds of 2:42 among subjects with undetectable cotinine (odds ratio = 18; 95 percent confidence interval = 3.3, 94). The validity of the assay was demonstrated by showing striking declines in adduct levels among quitting smokers. (*Am J Public Health* 1989; 79:1381–1384.)

Introduction

Involuntary exposure to tobacco smoke, or "passive smoking," has been found weakly associated with lung cancer in several epidemiologic studies, but several others have found no association.[1–3] Critics argue this evidence is flawed.[4,5] The International Agency for Research on Cancer (IARC) states that: "The observations on nonsmokers that have been made so far are compatible with either an increased risk from 'passive' smoking or an absence of risk. Knowledge of the nature of sidestream and mainstream smoke, of the materials absorbed during 'passive' smoking, and of the quantitative relationships between dose and effect that are commonly observed from exposure to carcinogens . . . leads to the conclusion that passive smoking gives rise to some risk of cancer."[3] Mantel[6] concludes that the relative risk of passive smoking is too low to be detected by epidemiologic studies.

If Mantel is right, assessment of the risk of passive smoking depends on measurement of the extent of absorption of carcinogens from tobacco smoke. No evidence has been reported to date of increased blood levels of a known carcinogen in passive smokers. We collected blood samples from nonsmokers with various degrees of passive exposure, classified them by plasma cotinine detectability, and measured levels of 4-aminobiphenyl and 3-aminobiphenyl covalently bound to hemoglobin. The adducts of these aromatic amines with hemoglobin (4ABP-Hb; 3ABP-Hb) are formed over the 120-day lifespan of the erythrocyte and therefore may serve as dosimeters of average exposure over the previous four months.[7] 4ABP is a known human carcinogen[8] and 3ABP, although not proven to be carcinogenic in humans, is a marker of 4ABP formation by pyrolysis[9] and has been shown carcinogenic in rats.[10]

Methods

Subjects

Nonsmokers were recruited by a variety of methods to cover a range of passive exposures. To represent chronic passive exposure, six heavily exposed nonsmoking bartenders were recruited by a telephone survey of local bars. To represent more normal but quantitatively uncertain levels of passive smoking, 21 nonsmokers who reported exposure to at least one pack of cigarettes per day were recruited by asking colleagues to survey their friends. To represent lack of exposure, 14 nonsmokers who reported negligible passive exposure in the past two months were recruited from our research staffs. Added to this was a group of blood donors in Italy who served as nonsmoker controls for another study.[11] The Italians were not selected according to their degree of passive exposure and therefore were presumed to be more representative of a cross-section of nonsmokers.

Exposure

Local volunteers, after completing a consent form, donated 10–20cc of blood, which was drawn into a vacuum tube containing EDTA (ethylenedinitrilotetraacetate) as anticoagulant and immediately placed in a cooler. Using a short standard questionnaire, subjects were interviewed about their exposure to tobacco smoke during the past two months. Questions included numbers of smokers in the work and home environment, and estimated numbers of packs of cigarettes per day smoked in their presence. Information on involuntary exposure to smoke was not available from of the Italian blood donors.

Plasma cotinine was measured by the laboratory of N.J. Haley of the American Health Foundation, Valhalla, NY. Four subjects were excluded for having cotinine levels that were suspicious of active smoking[12]: One local volunteer who claimed only passive exposure had 240 ng/ml of cotinine, and three Italians who had reported being nonsmokers had 61, 97, and 101 ng/ml of cotinine in their plasmas. The remaining subjects were divided into two groups: 1) undetectable cotinine, and 2) detectable cotinine. (The limit of detection of the cotinine assay was 2 ng/ml.) These two groups were then subdivided according to the level of exposure they reported in their interviews, as follows.

Group 1a (n = 14): Research workers; no cotinine; reported little or no passive exposure.

Group 1b (n = 15): Italian blood donors; no cotinine; no interview about passive exposure.

Group 1c (n = 15): Local volunteers, no cotinine; reported passive exposure to at least one pack of cigarettes per day.

© 1989 American Journal of Public Health 0090-0036/89$1.50

Group 2a (n = 7): Local volunteers; measurable cotinine; reported passive exposure to at least one pack of cigarettes per day, plus one Italian blood donor with measurable cotinine.

Group 2b (n = 6): Local bartenders; measurable cotinine; reported passive exposure to five or more packs of cigarettes per day.

Group 1b was ranked between Groups 1a and 1c because it presumably comprised a mixture of people who would have been assigned to Groups 1a or 1c if they had been interviewed.

Adduct Assay

The methods of sample preparation and analysis for determining the concentration of 4ABP adducts with hemoglobin have been described in detail.[13,14] In brief, hemoglobin was isolated from red blood cells and purified by dialysis. The dialysate was spiked with a nanogram of an internal standard (4'-fluoro-4-aminobiphenyl) and then hydrolysed with dilute base to release free 4ABP and 3ABP from the adducts. The amines were extracted into purified hexane and then derivatized to form the corresponding pentafluoropropionamides. These were quantified using capillary gas chromatography with detection by negative-ion chemical ionization mass spectrometry. The average limit of detection of the assay for 3ABP was 1.0 pg/g of Hb, calculated as the quantity of adduct necessary to produce a peak intensity three times the root mean square of the individual chromatogram's baseline noise level.

The precision of the assay was assessed by splitting two 100 ml blood samples into 8 and 7 aliquots.[14] The coefficient of variation of the estimates of 4ABP-Hb concentration, expressed in pg/g of Hb, was 10 percent for each sample. In addition, from 15 people with varying levels of 4ABP-Hb, duplicate blood samples were collected 15 or 48 hours apart. The coefficient of variation in 4ABP-Hb adduct concentration among duplicates was 9 percent, entirely attributable to variation in the assay technique. This suggested day-to-day biologic variation in adduct levels was negligible.

Validation Studies

To demonstrate the validity of the level of the hemoglobin adducts as dosimeters of human exposure, we recruited seven quitting smokers and measured adduct levels in blood samples drawn on the day they entered the stop-smoking program, and two months or more later. Serum cotinine was used to confirm that all seven had successfully quit. Further validation data were found in the results of a cross-sectional study conducted in Italy in which the dose-response relationship between intensity of smoking and adduct level was examined.[11]

Data Analysis

Since the distributions of adduct levels among passive smokers and unexposed nonsmokers were found to be skewed, nonparametric tests were used. The median two-sample test was the preferred basis for inference because it is relatively insensitive to outliers.[15] The Wilcoxon two-sample test was also used.[15] One-sided p-values were used because the hypotheses were directional.

Subjects with undetectable levels of 3ABP-Hb were handled in two ways. First, the subjects were assigned the highest level of 3ABP that could have gone undetected, given the noise level of each chromatogram. Second, the subjects were omitted from the analysis.

Results

Validity

We found striking reductions in adduct levels among quitting smokers. The mean level of 4ABP-Hb fell 75 percent from 130.4 pg/g Hb (s.e. = 35.1 pg/g Hb) at baseline to 33.3 pg/g Hb (s.e. = 7.3 pg/g Hb) after 2 months. The mean level of 3ABP-Hb fell at least 80 percent from 16.0 pg/g Hb (s.e. = 7.2 pg/g Hb) to a baseline of approximately 1.7 pg/g Hb (s.e. = 1.3). Only three of the seven subjects contributed to the estimate of the average final level of 3ABP-Hb because concentrations in the other four subjects were below the limits of detection of the assay.

The cross-sectional study of Italian smokers[11] showed dose-response relations existed between number of cigarettes smoked per day and levels of both 4ABP and 3ABP.*

Passive Smokers

The characteristics of each subgroup and the median and mean levels of 4ABP-Hb and 3ABP-Hb are shown in Table 1. The individual levels of 4ABP-Hb and 3ABP-Hb are plotted in Figures 1 and 2.

Levels of 4ABP-Hb were marginally higher in Group 2 than in Group 1 (Figure 1). The difference was of borderline statistical significance: the median two-sample test statistic was 1.64 (p = 0.05). The Wilcoxon two-sample test statistic was only 1.08 (p = 0.14) due to several atypically high values in Group 1. The highest value (152 pg/g) was from a woman who claimed passive exposure to 10 cigarettes per day but had no detectable cotinine in her blood. The next two highest values were from women in Group 1a. One woman with 89 pg/g confirmed on reinterview that she had had absolutely no

TABLE 1—Levels of 4-Aminobiphenyl and 3-Aminobiphenyl Adducts with Hemoglobin in Groups of Nonsmokers with and without Detectable Serum Cotinine, According to Level of Reported Passive Smoking

Group	Detectable Cotinine	Reported Passive Smoking	Number of Subjects	Mean Age	Percent Male	4-Aminobiphenyl*			3-Aminobiphenyl*†		
						Median	Mean	(S.E.)	Median	Mean	(S.E.)
1a	No	None	14	37	43	40	50	24	1.0	1.3	1.5
1b	No	—	15	39	100	37	42	15	1.0	1.2	0.6
1c	No	Yes, Low	15	28	26	38	46	31	1.2	1.2	0.7
2a	Yes	Yes, Low	7	32	86	42	45	14	0.7	1.5	1.3
2b	Yes	Yes, High	6	31	83	48	54	21	2.6	2.4	1.1

*Picograms of amine per gram of hemoglobin.
†Minimum detectable levels were used for subjects with undetected levels.

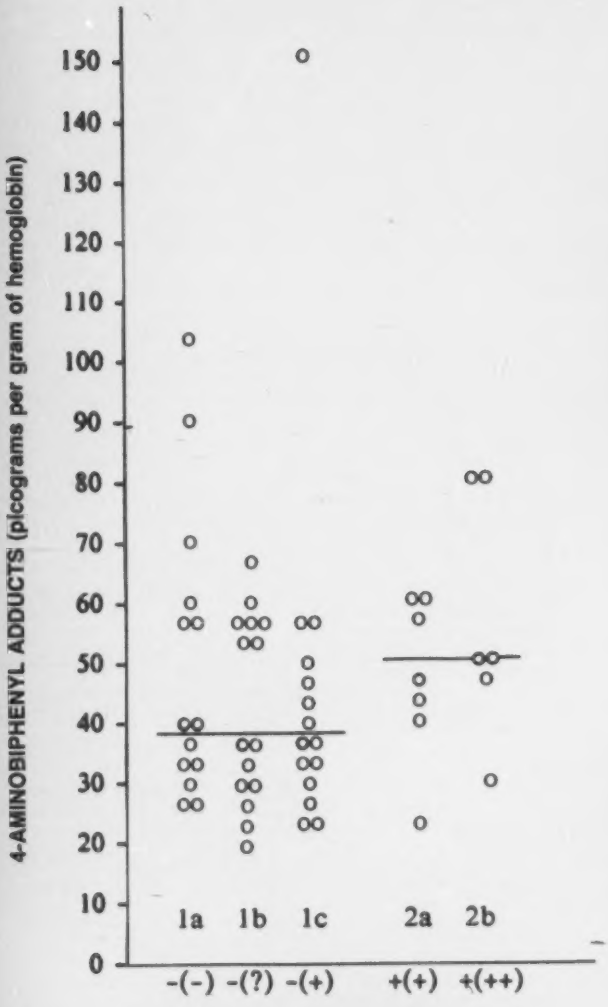

FIGURE 1—Levels of 4-Aminobiphenyl Adducts with Hemoglobin in Groups of Nonsmokers without (1a, 1b, 1c) and with (2a, 2b) Detectable Serum Cotinine, Indicated by − and + Signs.
Symbols in parentheses refer to self-reported level of passive exposure to tobacco smoke: (−) none; (?) unknown; (+) low; (++) high. Horizontal lines indicate locations of group medians.

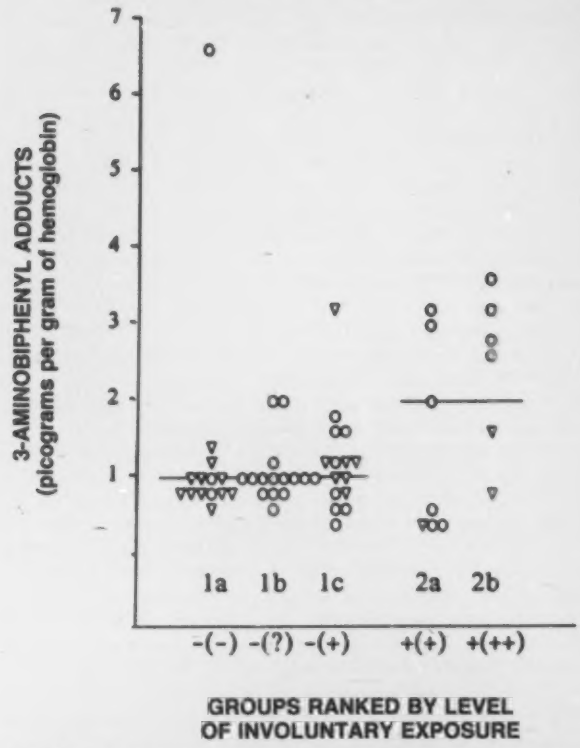

FIGURE 2—Levels of 3-Aminobiphenyl Adducts with Hemoglobin in Groups of Nonsmokers without (1a, 1b, 1c) and with (2a, 2b) Detectable Serum Cotinine, Indicated by − and + Signs.
Symbols in parentheses refer to self-reported level of passive exposure to tobacco smoke: (−) none; (?) unknown; (+) low; (++) high. Horizontal lines indicate locations of group medians. Triangles represent undetectable levels of adduct and are plotted at the highest level the subject could have had without detection.

passive exposure. Another, with 103 pg/g, reported only occasional mild exposure for short periods. Increasing the size of the control group by adding the seven exsmokers from the validation study resulted in a mean two-sample test statistic of 1.54 ($p = 0.06$) and a Wilcoxon two-sample test statistic of 1.41 ($p = 0.08$).

A clearer difference in the hypothesized direction was found for 3ABP-Hb levels (Figure 2). Group 2 had significantly higher levels than Group 1. The median two-sample test statistic was 1.92 ($p = 0.027$) and the Wilcoxon two-sample test statistic was 1.22 ($p = 0.11$), using the lowest detectable level for subjects with undetectable adduct levels. When undetectable levels were omitted, the median two-sample test statistic was 2.10 ($p = 0.017$) and the Wilcoxon two-sample test statistic was 1.65 ($p = 0.05$). The odds of a subject with detectable cotinine having a level of 3ABP-Hb greater than 2 pg/g of Hb were 6:7, compared with 2:42 among subjects with undetectable cotinine. The odds ratio was 18 with a 95 percent confidence interval from 3.3 to 94.

Discussion

Our observations corroborate the hypothesis that involuntary exposure to tobacco smoke results in higher levels of carcinogens in the blood. Subjects with plasma cotinine concentrations between 2 and 23 ng/ml had significantly higher concentrations of 4ABP-Hb and 3ABP-Hb than subjects with undetectable levels of cotinine.

The association with 4ABP-Hb was of only borderline statistical significance. However, it is less likely to be due to chance than the p-values indicate because the significant association with 3ABP-Hb provides additional evidence against the null hypothesis. It is well established that 3ABP forms in the same pyrolysis reactions as 4ABP.[9] Consistent with this, our validation study showed that 4ABP-Hb and 3ABP-Hb both declined among quitting smokers. Therefore, 3ABP-Hb is in part a marker of 4ABP exposure.

Nevertheless, the magnitude of the elevation in adduct levels was small relative to normal background levels. Non-tobacco sources of 4ABP, and perhaps 3ABP, appear to

exist. This was underscored by the fact that one woman with absolutely no passive exposure to tobacco smoke had levels of 4ABP-Hb higher than all the heavily exposed bartenders. Her level of 3ABP-Hb was undetectable, but another woman with minimal passive exposure had equally high 4ABP-Hb and the highest level of 3ABP-Hb in the study.

Since it is well established that 4ABP causes bladder cancer in humans,[8] our data suggest that risk of bladder cancer among heavily exposed passive smokers is slightly elevated. However, the increase in risk may be too small to detect in an epidemiologic study. A relative risk of 1.2 is regarded by many as the lower limit of detection in nonexperimental epidemiology. It is hard to detect a relative risk of 1.1 not just because of sampling variation but because of uncontrolled confounding. A potential confounding factor weakly associated with disease (relative risk = 1.7) could produce a spurious relative risk of 1.1 for passive smoking if passive smokers were twice as likely as unexposed nonsmokers to be exposed to the confounder.[16] A relative risk of 1.1 corresponds to a 10 percent excess in risk. For passive smoking to cause at least 10 percent excess in risk of bladder cancer, when active smoking causes an excess of only 100 percent (i.e., relative risk = 2), the excess concentration of activated carcinogens in the tissues of passive smokers should be approximately 10 percent of the excess in active smokers (assuming a linear relation between *in situ* dose and risk). In our data, the excess of adduct attributable to passive smoking appeared to be lower than this. Whereas the median level of 4ABP-Hb adducts in active smokers was found to be 200 percent to 400 percent in excess of the median level in unexposed nonsmokers,[10,13] the median level among passive smokers was only 10 percent to 20 percent in excess (i.e., the excess in passive smokers was 2.5 percent to 10 percent of the excess in active smokers).

Since our data are few, especially among confirmed passive smokers, and the assumption of linearity between adduct levels and risk is hypothetical, firm conclusions cannot be drawn. However, when compared with data that indicate cotinine levels in passive smokers are generally 1 percent, and at most 2–10 percent, the levels in active smokers,[3,17] our data seem more compatible with an undetectable rather than a detectable relative risk of bladder cancer due to passive smoking. One conclusion that does seem warranted, however, is that 4ABP does not conform to Remmer's hypothesis.[18] Remmer suggested that a larger proportion of inhaled carcinogens are metabolically activated in passive smokers, as compared to active smokers, due to the induction of detoxifying enzymes by substances in mainstream smoke that are not found in sidestream smoke. This does not appear to hold for 4ABP, assuming that the adduct with hemoglobin is a marker of the levels of activated 4ABP. There is evidence to support such an assumption.[13,19]

It is important to emphasize that "undetectable" does not mean "nonexistent." Since involuntary exposure to tobacco smoke is very common, even an undetectable relative risk such as 1.1 would be responsible for a great deal of avoidable cancer. The purpose of distinguishing between detectable and undetectable relative risks is for planning research to quantify the risk of passive smoking. If studies like ours show that post-activation levels of other tobacco carcinogens are much lower in passive smokers than active smokers, it will add weight to the view that quantification of the risk of passive smoking is beyond the capability of questionnaire-based epidemiologic studies, except when the association between active smoking and disease is very strong (e.g., relative risk of 10 for lung cancer). Risk assessment may instead depend on biochemical studies of carcinogen metabolites.

In conclusion, our results corroborate both the statement by the IARC that "passive smoking gives rise to some risk of cancer" and critics' contention that relative risks due to passive smoking may be undetectable.

Delayed Blood Regeneration in Lead Exposure: An Effect on Reserve Capacity

PHILIPPE GRANDJEAN, MD, PHD, BENT MØLLER JENSEN, MD, STEN HENRIK SANDØ, MD, POUL JØRGEN JØRGENSEN, MSC, AND STEEN ANTONSEN, MD

Abstract: Twenty-five lead-exposed Danish battery production workers and 25-age-matched controls were examined to evaluate subclinical effects on blood formation. Blood lead levels averaged 2.14 μmol/L and 0.35 μmol/L in the two groups; the lead workers also showed high levels of erythrocyte protoporphyrin, as compared to the controls. Otherwise, the hematological parameters indicated an appropriate iron status and no other deviations.

From all subjects, 0.45 L of blood was bled as part of a normal blood donation. Five and 11 days later, reticulocyte counts were significantly higher in the control group than in the lead-exposed workers. On day 15, the lead workers showed a significant delay in blood regeneration, as evidenced by lower hemoglobin concentration, and erythrocyte and reticulocyte counts.

The lead exposure in the present study was within legal limits, and lead-induced anemia would be expected only at much higher exposure levels. Thus, despite the normal hematological findings in the initial examination, the lead exposure caused a decreased reserve capacity for blood formation, and this effect became evident only after the blood loss. (*Am J Public Health* 1989, 79:1385–1388.)

Introduction

Although lead is one of the most extensively studied pollutants, the health significance of early hematological changes at slightly increased exposures remains unclear. Thus, heavy lead exposures are associated with low hemoglobin or anemia.[1,2] However, when blood-lead levels do not exceed 2.9 μmol/L, hemoglobin concentrations in male lead workers are usually entirely within normal ranges.[1–3] Despite the apparent absence of hematological abnormalities, such lead exposures reduce the lifespan of the erythrocytes and inhibit the heme biosynthesis.[4,5] These biochemical effects in a lead-exposed worker could place an increased strain on the bone marrow to keep the red-cell values within normal ranges.

Therefore, increased demand on the formation of blood following blood loss could result in a delayed blood regeneration in individuals exposed to lead. Only one experimental study has examined this question: dogs exposed to lead in the feed showed no delay in blood regeneration after a controlled bleeding.[6] However, lead exposure caused an unanticipated increase in the pre-hemorrhage hemoglobin as compared to controls in this study, and dogs may well differ from humans in their reactions to lead.

We have examined the blood regeneration following phlebotomy in men with occupational lead exposure and an age-matched control group.

Methods

Sample and Research Design

Based on a review of occupational lead exposures at nearby industrial facilities, two plants were selected for study: a battery factory with high lead exposures, and a tin can factory with minimal lead exposures. The safety committees at the two facilities helped identify possible volunteers among the long-term employees. Detailed information about the study was given to each participant. At each facility, informed consent was obtained from 25 healthy men who had never been blood donors before. The median duration of occupational lead exposure at the battery plant was seven years. The comparison group at the tin can factory was age-matched (within five years) with the participants at the battery plant. The median age in the exposed and the control groups was 39 and 36 years, respectively. The median length of employment in the control group was 10 years. Information on iron intake was not included in the matching criteria.

Phlebotomy (0.45 L) was performed in cooperation with the Blood Bank at the University Hospital. Due to practical constraints, the two groups went through the procedures at two different points of time; strict quality assurance efforts were therefore applied to ensure comparability of the results. Blood lead (B-Pb), erythrocyte Zn-protoporphyrin (ZPP) and indicators of iron status were determined only in samples obtained at the time of phlebotomy. Routine hematological parameters were subsequently assessed at days 5, 11, and 15 after phlebotomy; at day 15, signs of considerable blood regeneration would be expected.[7–10]

The protocol was prepared in accordance with the Helsinki II Declaration and reported to the local ethics committee.

Blood Lead

Blood samples for lead analysis were taken in Vacutainer vials with Na-heparin (dark-blue stoppers) (Becton-Dickinson, Rutherford, NJ) under conditions minimizing the risk of sample contamination. The samples were frozen at −80°C until analysis. B-Pb analysis was carried out by electrothermal atomic absorption spectrometry.[11] We used a Perkin-Elmer model 5000 instrument with Zeeman background correction, graphite furnace HGA-500, and autosampler AS-40 (Perkin-Elmer, Norwalk, CT). All results were read against a blood-based standard curve with standard reference material SRM 955 from the US National Bureau of Standards as primary standard. The total analytical imprecision was estimated to be 8.1, 2.1 and 1.9 percent at blood lead levels of 0.24, 1.63 and 2.96 μmol/L, respectively. Participation in international external quality assurance schemes showed deviations from the overall median between −8 and +11

percent for 14 blood samples, thus indicating a satisfactory accuracy.

Hematology

Hematological parameters were determined on fresh samples drawn in Venoject vials with Na_2EDTA (Venoject, Terumo Europe, Leuven, Belgium); special quality control procedures were used to minimize day-to-day variation.

ZPP was measured in oxidized blood on an Aviv hematofluorometer (Aviv, Lakewood, NJ).[12]

Erythrocyte count and hemoglobin concentration were determined on a Coulter Counter S using Coulter reagents (Coulter Electronics, Hialeah, FL). The instrument was whole-blood calibrated regularly and prior to each analytical series, and the calibration was controlled using the Coulter 4C Normal calibration material. Results for erythrocyte count and hemoglobin were accepted if within 2.7 percent and 2.6 percent, respectively, of the values assigned. Hematocrit was measured in duplicate by centrifugation (Sigma 2M, Christ, Osterode, Federal Republic of Germany) at 15,000 × G for 5 min using 75 mm borosilicate capillary tubes (Houmsen, Risskov, Denmark); the hematocrits were read with an Adams Micro-Hematocrit reader (Clay Adams, Becton-Dickinson, Parsippany, NJ) according to the NCCLS approved standard.[13] Mean cell volume and mean cell hemoglobin content were calculated from the erythrocyte count, hematocrit, and hemoglobin results.

Reticulocytes were counted in unfixed blood films following supravital staining with brilliant cresyl blue (1.5 g/L). Results are given as number of reticulocytes per 1000 erythrocytes.[14]

Serum iron (Fe^{3+}) was determined on a Prisma multichannel analyzer (New Clinicon, Stockholm, Sweden) at 600 nm after complex formation with 2,4,6-tri(2-pyridyl)-1,3,5-triazine following release from transferrin by hydrochloric acid and reduction by ascorbic acid.[15] We found a total coefficient of variation of 4 percent at an average of 31 μmol/L; the 95 percent reference interval using this method is 9–35 μmol/L.

Serum ferritin was measured by a sandwich radioimmunoassay (Bio-Rad, Richmond, CA) using an NE 1600 gamma-counter (Nuclear Enterprises, Edinburgh, Scotland). The total coefficient of variation was 6.2 percent at 366 pmol/L, 6.1 percent at 64.6 pmol/L and 15.0 percent at 13.5 pmol/L; the lower limit of the 95 percent reference interval is given by the manufacturer as 44 pmol/L for males below 45 years and 100 pmol/L for males above that age.

Serum transferrin and haptoglobins were determined by immunoturbidimetry in a Cobas Fara centrifugal analyzer (Hoffmann-La Roche, Basle, Switzerland).[16] We used antibodies from Dakopatts (Copenhagen, Denmark). For transferrin, the total coefficient of variation was 3.1 and 2.4 percent at mean values of 32.2 and 49.1 μmol/L, respectively; the 95 percent reference interval using this method is 24.5–39.0 μmol/L. For haptoglobins, the total coefficient of variation was 3.4 and 3.9 percent at mean values of 1.16 g/L and 1.80 g/L, respectively; the 95 percent reference interval for healthy individuals is 0.35–2.40 g/L.

Results

Lead Exposure

All B-Pb levels at the battery factory (Table 1) were higher than those seen at the control facility, but only one was above 2.9 μmol/L, a legal limit used in several countries. However, the median was above a proposed health-based limit of 1.9 μmol/L.[4] The ZPP levels overlapped only slightly between the two groups (Table 1), thus confirming the increased lead exposure at the battery factory and the expected interference with the heme biosynthesis.

Hematological Status

The hematological parameters showed minimal differences between the two groups (Table 1). The lead-exposed workers showed a slightly lower average haptoglobin level, and somewhat lower reticulocyte counts than did the controls. A few individuals in both groups showed high ferritin levels. Thus, in general, the hematological parameters indicated essentially normal conditions. Most importantly, no difference was seen in iron status between the two groups.

Effects of Phlebotomy

On days 5 and 11, the hematological parameters reflected the recent blood loss in both groups. In particular, the reticulocyte counts began to increase. However, on both occasions, the lead-exposed workers showed a significantly lower number of reticulocytes, as compared to the controls (Figure 1). Otherwise, no significant differences were seen between the two groups.

On day 15 after blood donation, both groups still showed significantly decreased hemoglobin, hematocrit and erythro-

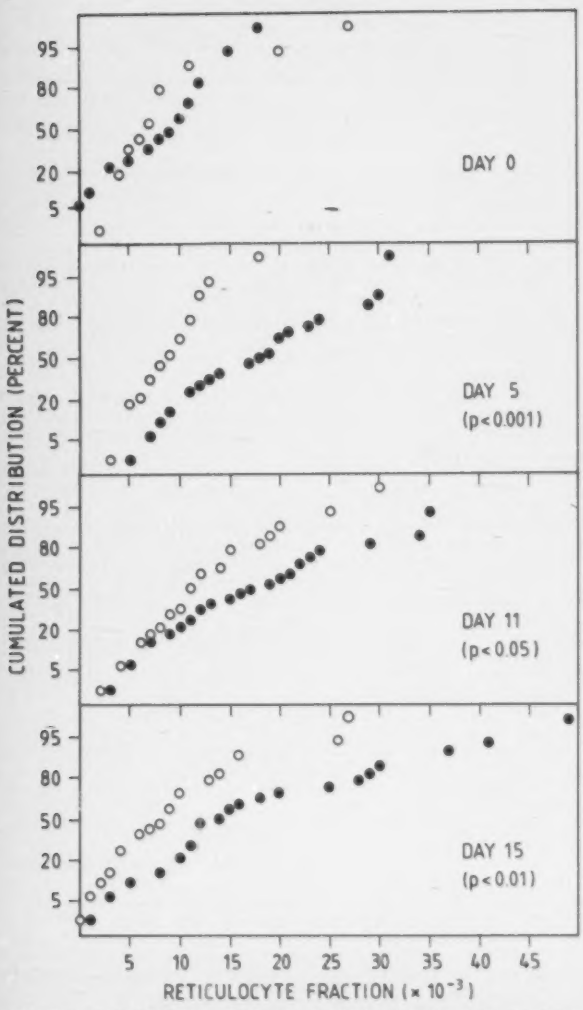

FIGURE 1—Cumulated Distribution (probability scale) of Reticulocyte Counts (per 1000 erythrocytes) at the Time of Phlebotomy (day 0), and 5, 11, and 15 Days Later (open circles, lead-exposed workmen; filled circles, age-matched controls).

cyte count, as compared to the day of phlebotomy. However, the decrease in hemoglobin and erythrocyte count was now significantly larger in the lead workers as compared to the control group ($p < 0.01$). As a further indication of the difference in blood regeneration activity, the increase in reticulocyte counts from day 0 to day 15 was less in the lead workers than in the controls (upper and lower panel of Figure 1).

When comparing the hematological data of the two groups at day 15, the high-lead group had significantly lower hemoglobin, and erythrocyte and reticulocyte counts, as compared to the controls (Table 2 and lower panel of Figure 1). No difference was seen in the hematocrit, mean cell volume, or mean cell hemoglobin.

Discussion

The cross-sectional data at the time of phlebotomy confirmed previous findings[1–3] that hemoglobin levels are within normal limits in male workers exposed to lead below the legal B-Pb limit of 2.9 μmol/L. The slightly decreased haptoglobin levels could be related to a lowered erythrocyte lifespan, as decreases in this parameter most often reflect hemolysis or dyshemopoiesis.[17] No significant tendency toward lower mean cell volume was found in the lead-exposed workers, although anemia in lead poisoning may be of the microcytic type.[4,5]

TABLE 2—Hematological Parameters in 25 Lead-Exposed Workers and 25 Age-Matched Controls 15 Days after Phlebotomy[a]

	Exposed Workers		Control Workers		
	Median	Range	Median	Range	P value

[b]Number per 10^3 erythrocytes.

The blood donation appeared to have similar effects on the two groups, except that the lead workers exhibited almost no increase in the reticulocyte count on day 5 and later lagged behind in reticulocyte counts. This deficient response to the blood loss is unexpected, because heavy lead exposure is known to cause an increase in reticulocyte counts, presumably as a result of the continuously increased demand on blood formation.[4,5]

Two weeks after phlebotomy, indications of increased blood formation should be apparent;[7–10] the findings in the control group concur with this pattern. However, the lower hemoglobin and erythrocyte count in the lead-exposed workers suggested delayed blood regeneration. No difference was detected in the hematocrit determination, perhaps due to the increased mean cell volume in the lead workers 15 days after phlebotomy. Although small, the differences in hemoglobin and erythrocyte count are considered valid, as comparability was ensured by vigorous quality control. Also, a delay in blood regeneration is in accordance with the slow increase in reticulocyte numbers seen in the lead workers.

Phlebotomy may be viewed as an artificial situation, but the half-liter blood loss is a reproducible intervention resulting in an increased demand on blood formation similar to, though probably less extensive than, the demand seen in a variety of medical conditions with excess blood loss. Also, this blood loss in blood donors represents an acceptable type of intervention that is known to cause no significant risk.

The present study of blood regeneration indicates that the reserve capacity was reduced in the lead workers despite the fact that minimal hematological changes were apparent before phlebotomy. In general, the level of erythropoiesis will depend on the marrow's capacity to proliferate, on erythropoietin stimulation, and on iron supply.[18,19] In the lead-exposed workers, the most important limiting factor in the rate of blood production after blood loss is likely to be the amount of available iron. As lead interferes with the utilization of iron in the bone marrow,[4,5] insufficient iron may be biochemically available for increased blood formation, despite a normal iron status. None of the subjects used iron supplements, and possible differences in dietary iron intake after blood donation would be unlikely to cause changes in iron status large enough to explain the differences in hemo-

globin and erythrocyte count. The biochemical indications of deranged heme biosynthesis and of decreased red-cell survival seen in lead-exposed workers would therefore appear to have physiological significance.

The decision whether or not a chemically induced change has any health significance is often difficult. However, decrements in reserve capacity would generally be regarded an adverse effect that should be prevented. Wide agreement seems to prevail on this point, despite international differences in preventive strategies, as evidenced, for example, by occupational exposure limits. Thus, according to a report from the US National Academy of Sciences, a nonadverse effect of a chemical exposure must not result in impairment of functional capacity or the ability to compensate for additional stress.[20] Similarly, in the Soviet Union, effects are regarded adverse or abnormal if departures from the generally accepted "normal" values become manifest under functional or biochemical stress.[21–23] A World Health Organization study group also expressed the need to protect against decrements in homeostasis or decreases in functional capacity and therefore initiated an effort to recommend health-based limits for occupational exposures.[4]

Unfortunately, studies on reserve capacity are few, and this lack of information hampers the detailed evaluation of chemical hazards. Thus, the theoretical approaches to prevention should inspire appropriate experimental and epidemiological studies to explore more fully how chemical exposures may interfere with homeostatic and compensatory mechanisms. With the multicausal etiology of many diseases, such subclinical effects of numerous environmental and occupational exposures may well be of importance. The present study has illustrated the possible significance of this concept.

OSHA awards $1 million in Job Safety and Health Education Grants

Secretary of Labor Elizabeth Dole recently announced that grants totaling $1 million have been awarded to eight labor and four employer nonprofit associations to continue developing job safety and health training and education programs. Since this "New Directions" effort began in 1978, OSHA has awarded approximately $81 million in job safety and health grants to 202 organizations.

Information about the "New Directions" program is available from the Occupational Safety and Health Administration Training Institute, 1555 Times Drive, Des Plaines, IL 60018. Tel: (312) 297-4810.

The Expense of Testing in a Teaching Hospital: The Predominant Role of High-Cost Tests

ROBERT M. HARTLEY, MD, MSc, MIRIAM A. MARKOWITZ, MSc, AND ANTHONY L. KOMAROFF, MD

Abstract: We analyzed all 32,206 tests ordered in a random sample of 1,000 patients admitted to a teaching hospital. The analysis examined costs instead of charges, included professional costs in addition to hospital costs, and considered the effect of combining tests that are ordered as a panel (e.g., cardiac enzymes) or as part of a procedure (e.g., bronchoscopy). High-cost tests (costing more than $100) accounted for only 4 percent of the total number of tests ordered, but for nearly 50 percent of total test costs. The pattern varied by clinical service: high-cost tests accounted for 31, 47, and 51 percents of total test costs on the obstetrics, medicine, and surgery services, respectively. It would seem to be efficient to concentrate on the use of high-cost tests in attempting to foster cost-effective use of diagnostic technologies. (*Am J Public Health* 1989; 79:1389–1391.)

Introduction

Many billions of dollars are spent each year on diagnostic technologies. How this money for diagnostic testing is spent remains unclear. While attention formerly focused on the use of high-cost tests, many have argued recently that the high volume ordering of inexpensive items may constitute the greatest fraction of total diagnostic testing costs.[1,2] Several reports have lent some support to this argument.[3,4] However, these studies have been designed to address other questions and have not attempted to measure directly the actual costs of testing.

Because of the importance of this issue in understanding how large sums of health care dollars are being spent and in choosing the best targets for cost-containment strategies, we have studied the cost of diagnostic testing in a sample of hospitalized patients. Because charges may poorly reflect true costs[5] and professional fees can add substantially to a test's cost, we have differentiated *costs* from *charges* and have examined both *hospital* and *professional* billing in our analysis.

Methods

Patient Sample

The Brigham and Women's Hospital in Boston, Massachusetts is a 720-bed tertiary hospital with an active teaching program. We randomly selected 1,000 patient admissions to the medical, surgical, gynecological and obstetrical services during fiscal year 1982. We included gynecological service patients with surgical patients since, in terms of resource consumption, they were more like surgical than obstetrical patients. Infants born in the hospital were excluded from the sampling frame. All data were obtained from and analyzed by a computerized system (CHASE System) built by one of us (AK), which stores itemized resource utilization data.

Definition of a Test

We defined a "diagnostic test" as any hospital procedure that was requested solely to seek information about a patient's status and which: required some sort of machinery; had been specifically requested in each instance of use; was not performed in a regular operating room; and did not involve continuous monitoring (e.g., central venous pressures) for an undefined time period. Using this definition, we examined all tests ordered in the sample of 1,000 patients: 1,195 different types of tests, ordered on 32,206 occasions.

We arbitrarily defined a high-cost test as one costing $100 or more, and a low-cost test as one costing less than $100.

Hospital Charges and Costs

We chose to estimate costs by two standard methods: ratios of costs-to-charges (RCCs) and relative-value units (RVUs). RVUs were either taken from College of American Pathologists standards, or developed through time-motion studies in our laboratories. RCCs were developed internally through detailed analyses of the laboratory's direct costs: the salaries of all personnel, including the physician laboratory director; supplies and equipment; and allocated expenses from all non-revenue producing cost centers, using a methodology that has been described in detail elsewhere.[6,7]

Analysis revealed no important differences when costs were estimated by the RCC or RVU method. Hereafter, all cost estimates are based upon RCC methodology.

Professional Charges and Costs

Because radiological, medical, and surgical professional groups billed separately for their services, we reviewed their billing data for each of our 1,000 patients. Pathology and cytology services did not bill separately for professional services. However, because professional labor constitutes a major proportion of these services' costs, we identified and separated the professional cost components. Routine hematology and chemistry professional costs were not separated because these professional costs contribute a very small proportion to their respective total test costs.

No reliable measures of true professional costs were available. Of available sources, the 1982 Medicare Part B customary reimbursements appeared to best express the direct costs of physician time and the indirect allocated costs of his or her business. However, because these estimates are likely in some cases to overestimate costs, we have conducted all analyses with and without professional costs

included. Conclusions about the relative contribution of high-cost items were not substantially affected.

Determination of Unit Cost of Each Type of Test

The unit cost of each type of test included both the hospital cost and, if there was one, the professional cost. In addition we aggregated the costs of several tests when they were ordered simultaneously for the same clinical purpose.

Specifically, this was done in two instances: 1) *Test panels*: whenever several clinically-related tests (e.g., cardiac enzymes or electrolytes) were ordered on the same day; 2) *Procedures*: whenever a diagnostic procedure was performed which of necessity generated a number of different tests (e.g., a lumbar puncture which required measurements of cerebrospinal fluid glucose, protein, cell count, culture, and cytology) in order to complete the diagnostic intervention.

We examined the impact on our conclusions of these aggregations and found that test panels predominantly involved low cost tests which, even when aggregated, remained low-cost items under $100 and mostly under $10. The disaggregation of test panel-related and procedure-related tests did not materially change the ratio of high-cost to low-cost tests. Hence, all results reported involve aggregation of test panel- and procedure-related tests, a process which we believe make most clinical sense.

Results

Patient Sample

Our random sample of 1,000 patients was representative of the more than 25,000 patients (except newborns) admitted to Brigham and Women's Hospital between October 1, 1981 and September 30, 1982; age, sex, distribution by service, length of stay, and mean charges were virtually identical.

Volume and Total Costs

All Tests—For our sample of patients, physicians ordered 32,206 tests, which generated $763,108 in hospital charges, $554,811 in hospital costs, and $121,303 in professional costs. Test volume and costs, per patient-hospitalization, varied greatly across the services, with costs for an average medical admission being nearly 14-fold higher than for an average obstetrical admission (Table 1). The professional fee component of test costs averaged 12–19 percent of total test costs on each hospital service (Table 1).

Low-Cost and High-Cost Tests—Low-cost tests were ordered in high volume, accounting for 96 percent of the number of all tests ordered; 68 percent cost less than $10; 85 percent cost less than $20.

Total hospital test costs had two major peaks which occurred at the opposite ends of the distribution. The low-end peak was accounted for by the high-volume low-cost tests; non-angiographic radiology procedures dominate the mid-range ($100–500 each) and various angiographic investigations primarily account for the high-end peak (greater than $500 each), as shown in Figure 1.

High-cost tests accounted for about 50 percent of total costs; tests costing more than $245 accounted for nearly 30 percent of total costs (Figure 2).

TABLE 1—Test Usage and Costs Per Patient On Each Hospital Service

Hospital Services	Number of Tests	Hospital Test Costs	Professional Test Costs	Total Test Costs
Obstetrics	8.6	$ 85.72	$ 11.70	$ 97.42
Surgery & Gynecology	34.7	636.29	145.33	781.62
Medicine	62.4	1108.97	240.07	1349.04
Average for All Services	32.0	554.81	121.30	676.11

Professional Costs

Professional costs contributed 17.9 percent of total costs. The cumulative distribution of professional costs, plotted according to the total test cost with which it was associated, paralleled that of total costs (Figure 2). In fact, the majority of the professional costs were incurred by tests costing less than $60, indicating that the inclusion of professional costs did not cause high-cost items to become the major contributors to total test costs.

Differences: Medical, Surgical, and Obstetrical Services

Diagnostic testing costs accounted for 14 percent of total hospital costs (professional costs excluded) in the total sample of 1,000 patients: 20 percent on the medical service, 12 percent on the surgical service, and 5 percent on the obstetrical service.

In surgery and medicine, expensive tests made the predominant contribution. High-cost tests accounted for 31, 47, and 51 percent of total test costs on the obstetrical, medical and surgical services, respectively (Figure 3). Tests costing more than $450 accounted for about 20 percent of total test costs for medical and surgical patients but none of the costs for obstetrical patients.

Discussion

Diagnostic testing makes a large contribution to the costs of care for hospitalized patients. Our results indicate that tests costing $100 or more account for one-half of the total diagnostic costs. We made the inherently arbitrary decision to define unit test costs of $100 or greater as "high-cost" because the distribution of total test costs by unit costs (Figure 1) demonstrated a natural break point at this level. The next natural break point occurred at $175, a substantially greater unit cost, and the unit prices for such tests were typically well over $200; it did not seem that most people would use the phrase "low cost" to apply to such tests. It is especially interesting to note the very large contribution to total test costs by tests whose unit costs were greater than $500 (Figure 1).

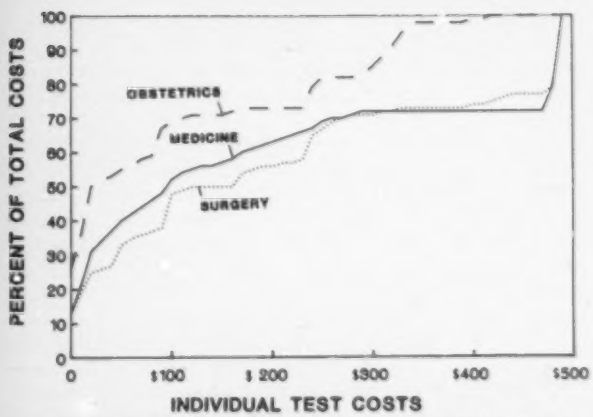

FIGURE 3—Cumulative Distribution of Total Test Costs, by Unit Cost of Each Type of Test Ordered, for each Hospital Resource Utilized, in 1,000 Randomly Selected Patients, 1982.

We believe the distinction we have made between high-cost and low-cost tests is useful for several reasons. First, attempts at control of the use of most high-cost items have traditionally employed regulatory measures directed at the capital expenditures needed for test machinery, an approach of no value for modifying low-cost testing. Second, reported experience suggests that at least one cost containment strategy, organized educational programs, may be less effective in reducing the use of high-cost than low-cost technologies.[4,8] Finally, test-ordering habits vary with test cost. Low-cost tests are often repetitively or reflexly ordered before information is available as to whether they are needed, whereas higher cost tests are usually sequentially ordered depending upon results from preceding investigations.

Our conclusions about the dominant contribution of high-cost items were unaffected by the inclusion or exclusion of professional costs. However, the contribution of professional costs to total test costs is nevertheless substantial. In our study, it represented more than 20 percent of the total for medical and surgical patients. In those situations where the test-ordering physician is the same as the test-performing physician—such as endoscopy or various cardiology procedures—the magnitude of the professional reimbursement represents an incentive for ordering and thus an additional challenge for cost-containment attempts.

Several aspects of our methodology should be noted. Our hospitalized patients were in a teaching center. In such a setting, the test-ordering physician is relatively inexperienced; there is easy access to costly test machinery and procedures; and patients may be more severely ill.[9] For these reasons, our findings may not be generalizable to nonteaching hospitals. On the other hand, we may have underestimated the contribution of high-cost tests, even at a teaching hospital: we did not include as high-cost items several *therapeutic* procedures which have diagnostic components (e.g., laparoscopy, arthroscopy).

While low-cost tests may contribute more in other settings, our results indicate that high-cost tests make an important—in this study, predominant—contribution to the costs of diagnostic testing. Cost containment efforts should target strategies designed to ensure effective use of high-cost tests.

ACKNOWLEDGMENTS

We would like to thank Larry Williams and Charles Daschbach, MD, for their important contributions. Dr. Barbara J. McNeil was helpful in initial discussions about experimental design. This research was supported by grants from the Commonwealth Fund; the John A. Hartford Foundation; and the Blue Cross/Massachusetts Hospital Association Fund. The Mortality Consequences of Raising the Speed Limit to 65 MPH on Rural Interstates

HERBERT M. BAUM, PHD, ADRIAN K. LUND, PHD, AND JOANN K. WELLS, BA

Abstract: As of April 1987, states were permitted to raise the speed limit on rural interstates to 65 mph without incurring federal sanctions; 38 states elected to do so in 1987. Fatality data for the months when the new limit was in effect in 1987 were compared with fatalities in the same months of 1982–86 on rural interstates and other rural roads. Fatalities on rural interstates in the states with increased speed limits in 1987 were conservatively estimated to be 15 percent higher than they would have been if the states had retained the 55 mph limit (95% CI = 6, 24). Among states that retained the 55 mph limit, fatalities on rural interstates were 6 percent lower than expected (95% CI = −23, 13). (*Am J Public Health* 1989; 79:1392–1395.)

Introduction

Speed limit laws, which date back to 1901, have traditionally been the responsibility of the states. However, in 1974, Congress responded to the oil embargo by directing the US Department of Transportation to withhold highway funding from states that did not adopt the national maximum speed limit of 55 mph (PL 92-239 and 93-643).

The National Research Council (NRC) attributed 4,000 fewer fatalities from 1973 to 1974 to the decreased speeds. Despite some increases in travel speeds since 1974, the NRC concluded that in 1983 the 55 mph speed limit was responsible for approximately 3,000 fewer fatalities, 3,500 fewer serious, severe, and critical injuries, and 47,000 fewer minor and moderate injuries.[1] The NRC estimated that returning the speed limit on rural interstates to their pre-1974 level in all states would result in 500 more fatalities annually, a 20–25 percent increase on these highways.[1]

In 1987, Congress enacted the Surface Transportation and Uniform Relocation Act (PL 100–17), which allowed states to increase the speed limits on rural interstate highways up to 65 mph. By the end of 1987, 38 states had raised their speed limits on rural interstates to 65 mph. Two additional states, Georgia and Virginia, followed suit in 1988. The District of Columbia, Delaware, and Alaska had no eligible miles of highway, leaving eight states with eligible mileage that have not increased speed limits (Figure 1). In December 1987, Congress established a four-year demonstration project that expanded the list of eligible highways to include turnpikes and other highways that meet federal interstate standards. Consequently, Alaska increased the speed limits to 60 mph on some roads, and some other states raised the speed limit on non-interstate rural roads.

Recent observational studies in several states found that, although the previous 55 mph speed limits had been exceeded frequently, the increased speed limits resulted in more motorists traveling at faster speeds.[2] In New Mexico, the percentage of passenger cars exceeding 65 mph went from 37 percent in the first month of implementation to 61 percent in the eighth month; the percentage of passenger cars exceeding 70 mph quadrupled, from 5 percent to 21 percent. In Virginia, the percentage of passenger cars exceeding 65 mph went from 26 percent immediately before the change to 54 percent immediately after, and the percentage exceeding 70 mph went from 7 to 15 percent.[3]

The National Highway Safety Administration (NHTSA) issued a report in January 1989 on the effects of the higher speed limit. NHTSA noted that it was too early to assess the long-term impact of the new speed limit on highway safety. However, the most sophisticated of the report's analyses (a regression model that controlled for fatalities on other roads, and the change in rural interstate mileage, for each year since 1975) indicated that rural interstate fatalities were 16 percent higher than expected.[4]

An American Automobile Association (AAA) sponsored analysis of the effect of the 65 mph limits in Indiana showed no effect on fatalities.[5] However, individual state analyses can often be misleading because the number of crashes on rural interstates are few and the statistical variation associated with these counts can be quite large. In Indiana, for example, there are about 90 fatalities annually on rural interstates. By chance, this count would vary by as much as 20 percent (the standard error of a Poisson distribution with a mean of 90 is ± 9.5). Further, one month after the speed limit was raised, Indiana's mandatory seat belt use law went into effect, and the AAA analysis did not adequately address this change.

This paper presents analyses of fatalities on highways with increased speed limits for the 38 states that raised limits in 1987. By including all these states, the analysis minimizes the problem of statistical unreliability inherent in individual state analyses. In addition, to help control for other contemporaneous changes that might affect fatal crashes on rural interstates, the analysis also examined the fatal crash experience on other roads that might be expected to respond

similarly to many of these changes. Fatality data for the months of higher limits in 1987 were compared to the average for the same months during the previous five years.

Method

Fatality data are from the Fatal Accident Reporting System (FARS), the federal data base of detailed reports on all fatal motor vehicle crashes on public roads in the United States.[6] States enacted the higher speed limits on various dates throughout 1987 (Table 1). As shown in the table, fatalities on rural interstates in 1987 were counted for each state for all months following the month in which the speed limit was raised to 65 mph. For example, in Alabama where the increased limit became effective on July 20, fatalities were included for August through December. The month in which the change occurred was excluded because of possible delays in posting signs. Rural interstate fatality counts were also obtained for the same calendar months in each of the previous five years, 1982–86. Both overall fatality counts and counts of fatalities among occupants of passenger vehicles (cars, light trucks, and vans) were examined.

Under the 1987 law, a state can post a 65 mph limit on a "highway on the interstate system located outside of an urbanized area of 50,000 or more persons." This definition of eligible highways does not correspond exactly with the highway designations used in FARS; all interstates in FARS that are coded as rural meet the Act's definition, but a small percentage of FARS designated urban highways also meet the definition. However, because 96 percent of the interstate highway miles eligible to be posted at 65 mph are rural interstates as defined by FARS, and 97 percent of these eligible miles were posted at higher limits, these highways were used to represent those with 65 mph limits.[4] An alternative way to count fatalities was to tabulate using the actual posted speed limit recorded in FARS to indicate eligible highways; however, this approach would have precluded comparisons prior to 1987.

Because motor vehicle crash fatalities fluctuate from year to year for a variety of known and unknown reasons, changes observed on rural interstates might be due to other trends in motor vehicle crashes. Therefore, fatality counts on rural interstates were compared to those on all other rural roads.

The odds that a fatality occurred on a rural interstate road (versus all other roads or all other rural roads) were compared to the same odds averaged over the previous five years (1982–86). The 95 percent confidence limits for this odds ratio were computed by methods given in Fleiss.[7]

The fatality experience of states that increased the speed limit was not compared directly to the experience of states that retained the 55 mph limit. As shown in Figure 1, most states that retained the 55 mph limit are in the densely populated northeast and differ on a number of factors that could affect traffic fatalities. In addition, the fatality experience of these states may have been affected by the spillover of higher speeds from states that changed, thereby making a direct comparison inappropriate. Nevertheless, the fatality experience of the states that retained 55 mph limits was examined for any evidence that changes in the 65 mph states were simply part of a larger national trend. Odds ratios, similar to those for the 38-state analysis, were constructed using data from eight states (Connecticut, Georgia, Maryland, Massachusetts, New Jersey, New York, Pennsylvania, and Virginia) that had 55 mph limits and at least 25 miles of rural interstate highway. Fatalities were counted only during the months of May through December to simulate a speed limit change in April of 1987. If there were no larger national trend in rural interstate fatalities in 1987, this odds ratio would be expected to equal unity.

TABLE 1—Effective Dates for 65 mph Speed Limit and Months of Data Included in Analysis, 38 States

State	1987 Effective Date	Analysis Months
Alabama	July 20	August–December
Arizona	April 15	May–December
Arkansas	April 20	May–December
California	May 28	June–December
Colorado	April 6–10	May–December
Florida	April 27	May–December
Idaho	May 2	June–December
Illinois	April 27	May–December
Indiana	June 1	July–December
Iowa	May 12	June–December
Kansas	May 14	June–December
Kentucky	June 8	July–December
Louisiana	April 8	May–December
Maine	June 17	July–December
Michigan	November 29	December
Minnesota	June 17	July–December
Mississippi	April 14	May–December
Missouri	May 1	June–December
Montana	April 16	May–December
Nebraska	April 27	May–December

Utah	May 21	June–December
Vermont	April 21	May–December
Washington	April 20	May–December
West Virginia	April 20	May–December
Wisconsin	July 17	August–December
Wyoming	May 19	June–December

Results

The numbers of fatalities on rural interstates during the months with higher speed limits in 1987 and the same months in 1982–86 for the 38 states with changed limits are shown in Figure 2. This figure shows that fatalities on rural interstates posted with 65 mph limits in 1987 were considerably higher than in any of the previous five years.

Although the number of fatalities on rural interstates increased slightly over the five baseline years, a similar trend was also found for the control series of fatality counts on other rural roads. The yearly odds of fatalities on rural interstates compared to other rural roads remained fairly constant until 1987. Specifically, for 1982 through 1986, the ratios were 0.097, 0.106, 0.109, 0.107, and 0.100, respectively.

There were 19 percent more fatalities on rural interstates in 1987 than the average for the previous five years, while there were only 4 percent more fatalities on other rural roads. For all fatalities, the odds of death on rural interstates versus other rural roads were 15 percent (95% CI = 6, 24) greater in

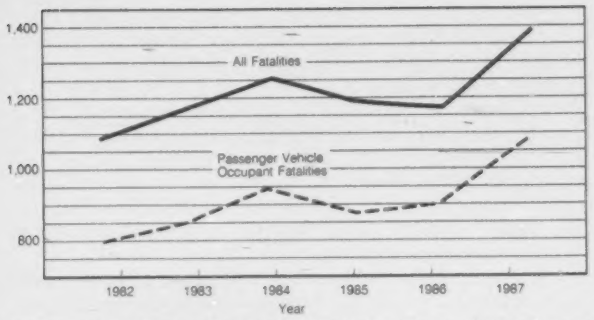

FIGURE 2—Fatalities on Rural Interstates during Months of Higher Speed Limits in 1987 and Same Months in 1982–86

1987 than the average for 1982–86 (Table 2). If *all* other roads are used for the comparison, the ratio yields a 16 percent effect.

The odds ratio for passenger vehicle occupant deaths showed a similar increase—16 percent (95% CI = 6, 28). There were 25 percent more passenger vehicle occupant fatalities on rural interstates in 1987 than the average of the previous five years, while on other rural roads the increase was only 8 percent. When all other roads were used as the comparison group, the odds for passenger vehicle occupant fatalities on rural interstates were 17 percent higher than expected.

A number of other factors that might affect the relation between speed limit changes and fatalities were also examined. These factors included different speed limits for cars and trucks, mandatory seat belt laws, daytime (6 am–9 pm) versus nighttime crashes, and the proportion of single or multiple vehicle fatal crashes. These analyses were done by subdividing the data for rural interstates and other rural roads for all fatalities by the appropriate factor and comparing the odds ratios. The estimated effect of 14 percent for the eight states with different speed limits for cars and trucks (California, Illinois, Michigan, Missouri, Ohio, Oregon, Texas, and Washington) was similar to the 15 percent effect for states with uniform limits. The effects were also similar in states with belt use laws (15 percent) and without belt laws (13 percent). For daytime and nighttime crashes, the effects were also similar (16 percent and 14 percent). The effect for fatalities involving single vehicles was 17 percent, and for fatalities involving multiple vehicles it was 10 percent. A test for homogeneity of the odds ratios was not significant implying no difference between the odds ratios.

The analysis for the eight states that retained 55 mph limits in 1987 indicated no effect during the comparison period. There was a 4 percent increase in all fatalities on rural interstates, but this was offset by an even larger increase on other rural roads (12 percent). The estimated odds ratio was 0.94 (95% CI = 0.77, 1.13).

Discussion

In the 38 states that set higher speed limits in 1987, fatalities on rural interstates were conservatively estimated to be 15 percent greater than they would have been if the states had retained the 55 mph limit on these roads. Increased fatalities were seen in 24 of the 38 states. In human terms, there were nearly 200 additional fatalities in 1987 during the months when the higher speed limits were in effect. This number will be larger for 1988 because two additional states have raised their speed limits, more miles of highways were eligible, and states will have had a whole year of experience.

In a 1988 interim report on the effect of the higher speed limit, NHTSA had expressed concern that the observed 1987 increase in fatalities began in the months prior to initiation of the higher limits.[8] To test this possibility, an alternative analysis examined fatalities for January through March of 1987 versus those for 1982–86. The odds ratio for fatalities on rural interstates versus other rural roads indicated that fatalities on rural interstates were about 6 percent higher than expected during the first quarter of 1987. Although the odds ratios in Table 2 could be adjusted for this first quarter increase, the odds ratio for the first quarter included 1.0 suggesting that the observed difference was due to random fluctuation. In addition, fatalities during winter months tend to fluctuate greatly from year to year because of varying weather patterns, and the current analysis could not control for these patterns. Moreover, there is the possibility that some drivers began increasing their travel speeds even before the speed limits were raised. Such anticipatory speed increases could have been triggered by news reports and publicity regarding possible federal action in early February and again in March.[9,10] For these reasons, it would have been inappropriate to adjust the estimated effects of the higher speed limits for the nonsignificant differences observed in January through March.

The estimated 15 percent increase in these data is somewhat smaller than the 20–25 percent increase predicted by the NRC partly because of the NRC assumption that all states would return to pre-1974 speed limits, often 70 and 75 mph. Because the energy associated with a crash increases exponentially with the speed of the crash, the likelihood of serious injury and fatality increases very rapidly as travel speeds increase in this range.[11] Therefore, even larger effects

TABLE 2—Number of Fatalities by Road Type and Time Period for All Fatalities and Passenger Vehicle Occupants

	Average 1987 Number	Average 1982–86 Number	Chi-Square Statistic	Odds Ratio	(95% Confidence Limit)
All Fatalities					
Rural Interstates	1,393.0	1,169.2			
vs Other Rural Roads	11,713.0	11,259.2	10.40	1.15	(1.06, 1.24)
vs All Other Roads	19,607.0	19,110.2	13.20	1.16	(1.07, 1.26)
Passenger Vehicle Occupants					
Rural Interstates	1,084.0	864.8			
vs Other Rural Roads	9,321.0	8,632.4	9.53	1.16	(1.06, 1.28)
vs All Other Roads	13,906.0	13,031.8	11.50	1.17	(1.07, 1.29)

than estimated here would have been expected if states had returned to these higher limits.

In addition, the 15 percent increase in fatalities found here probably underestimates the true effect of the 65 mph limits. The effect was measured by comparing the odds of a fatality on rural interstates to other roads. If higher travel speeds on rural interstates spill over onto some of these roads, as suggested by research on speed adaptation, then the number of fatalities would have increased on these other roads as well.[12–14] Such a spillover would reduce the estimated effect (but not the true effect) of the higher speed limits as measured in this analysis.

The NHTSA report highlighted two factors that argued against a large increase in fatalities attributable to the 65 mph speed limits: the states that did not increase their speed limits also had an increase in fatalities on rural interstates and six states accounted for 64 percent of the excess fatalities in 1987.[4] The current analysis examined the odds ratio for the unchanged states for 1982–86 versus 1987 and found rural interstate fatalities were marginally fewer than expected for May–December of 1987 in states that retained 55 mph speed limits. Thus, there is no evidence of a larger national trend toward more fatalities on rural interstates in 1987.

When odds ratios were computed for each state, they were greater than unity in 24 states. Therefore, despite the dominance in the absolute numbers by six states, the trend of higher crash fatalities on rural interstates than on other rural roads was observed in more than three of five states that increased their speed limits. The fact that rural interstate fatality counts were not higher than expected in a minority of states is consistent with the statistical uncertainty associated with analyses of data from individual states.

In summary, the results of this analysis show that the 65 mph limits increased rural interstate fatalities in 1987 by approximately 15 percent, there was no evidence of a similar trend in states that retained 55 mph limits, and the increase was not limited to only a few states.

ISHIB Calls for Abstracts on Hypertension in Blacks

The 5th International Interdisciplinary Conference on Hypertension in Blacks has issued a call for abstracts for its conference, to be held May 3–7, 1990 in Long Beach, California. The announced theme for the meeting is: "A Focus on Ethnicity: Negroids, Caucasoids, Mongoloids." The deadline for abstract submission is November 1, 1989.

Sponsored by the International Society on Hypertension in Blacks (ISHIB) and by a cooperative of health organizations from throughout the world, the conference is to be hosted by the Charles R. Drew University of Medicine and Science, the University of California at Los Angeles, and the University of Southern California. For registration information, abstract guidelines, and forms, contact: ISHIB, 69 Butler Street, SE, Atlanta, GA 30303, USA. Tel: (404) 589-3810; FAX: (404) 688-5169.

Homicide, Suicide, Motor Vehicle Crash, and Fall Mortality: United States' Experience in Comparative Perspective

IAN R.H. ROCKETT, PHD, MPH, AND GORDON S. SMITH, MB, CHB, MPH

Abstract: US mortality data on motor vehicle crashes, falls, suicide, and homicide for 1980 are compared with corresponding data for France, Japan, West Germany, and the United Kingdom. Unadjusted and age-specific death rates are presented, together with age-adjusted rates of years of life lost (YLL). A large male excess in rates is typical outside the fall category. Motor vehicle crashes are the predominant cause of YLL, and the United States manifests the highest YLL rates for each sex. US fall death rates at the older ages are exceeded by those of France and West Germany. The elderly generally manifest the greatest risk of suicide; American females exhibit a unique rate decline after ages 45–54 years, however. Beyond early adulthood, US suicide rates are lower than those of France, Japan, and West Germany. US homicide rates dwarf those of the comparison countries with 16- to 29-fold differentials separating prime-risk American males aged 25–34 years from their foreign counterparts. (*Am J Public Health* 1989; 79:1396–1400.)

Introduction

In a foreword to an influential report from the National Academy of Sciences, William Foege remarked on the persistence of injuries as a "major determinant of longevity" in the United States, and globally.[1] The 1980s have furnished much basic data on injury occurrence and witnessed renewed interest in their prevention.[2–7] Federal Government support has been strengthened by the formation of a Center for Environmental Health and Injury Control at the Centers for Disease Control, the establishment of five regional university-based injury prevention research centers, and growing sponsorship of pertinent research projects and prevention programs by the National Institutes of Health.[8,9]

Nationally, injuries rank fourth as a cause of death behind heart disease, cancer, and cerebrovascular disease,[10] but they are the premier killer of Americans between ages one and 45 years,[10] and are the leading cause of years of life lost (YLL) before age 65.[11] An international study revealed marked differences in all-cause injury death and age-adjusted YLL rates for the United States, France, Japan, the United Kingdom, and West Germany.[12] The aim of the present paper is to shed light on these findings through an examination of data on unintentional motor vehicular and fall mortality, suicide and homicide—the leading causes of injury mortality in the United States.[4] The four comparison countries are of particular interest due to similarities they share with the United States in terms of development and mode of government, and because of their close political and economic links to this country. All five countries have populations exceeding 55 million, and thus may be considered demographically large.

Methods

Data are adapted from 1980 age-, sex-, and cause-specific mortality tabulations published by the World Health Organization (WHO).[13] Total injury deaths (E800–E999) and deaths from motor vehicle traffic crashes (E810–E819), falls (E880–E888), suicide (E950–E959) and homicide (E960–E969) are classified under an abbreviated three-digit external cause code according to the basic tabulations list of the ninth revision of the *International Classification of Diseases* (ICD-9).[14]

YLL rates are adjusted for age by means of a direct standardization procedure,[15] using the 1980 US population as the reference. YLL represent the summation of the products of the number of deaths at each age, here starting at age one, and the years of life remaining up to the age ceiling, here age 65. Since the WHO age data are abridged, age at death for decedents is estimated as the mid-point of the respective age groups.

Results

Crude Rates and Causal Components

France manifests the highest crude injury death rates for either sex (116 per 100,000 males and 73 per 100,000 females) (Table 1). The United States has the second highest rate for males (105 per 100,000), West Germany the second highest rate for females. Male rates surpass female rates in all five countries, and the magnitude of the male excess ranges from 50 percent in the United Kingdom to 180 percent in the United States.

Motor vehicle crashes, falls, suicide, and homicide collectively account for between two-thirds and four-fifths of total injury deaths in each country. However, homicide is a major cause of death only in the United States. Homicide rates in the remaining four countries approach individual mortality rates for fire, poisoning, drowning, and other transportation (data not shown).

Except in Japan, motor vehicle crashes are the leading cause of injury mortality among males, with the United States having the highest sex-specific rates. Motor vehicle crashes are also the leading cause of injury mortality among females in the United States, but in the remaining countries they are surpassed by suicide, falls, or both. Male predominance universally characterizes motor vehicular mortality and suicide, but the sex differential is sharply reversed with respect to fall mortality in France, West Germany, and the United Kingdom.

Age-Specific Rates

Both sexes exhibit a bimodal age-specific pattern of motor vehicular mortality, irrespective of country (Figure 1). Peaks occur at ages 15–24 years and over 74, with male rates greatly exceeding female rates. Japan and the United King-

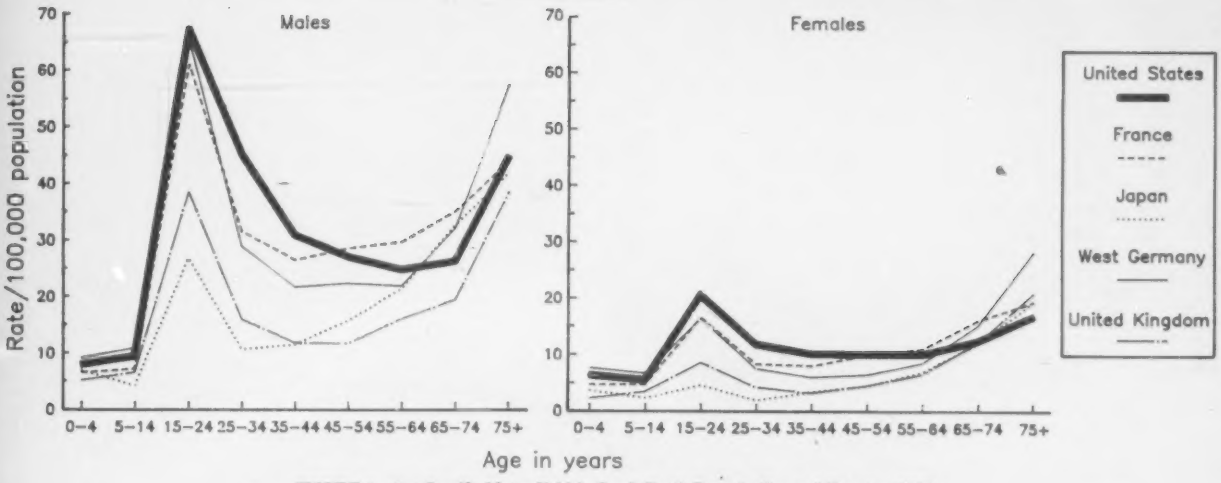

FIGURE 1—Age-Specific Motor Vehicle Crash Death Rates by Sex and Country, 1980

dom manifest the lowest motor vehicular death rates for both sexes, although there is a trend toward convergence at the upper end of the age spectrum. The United States has the highest motor vehicular death rate for females from ages 15 through 44 years, and the lowest rate in the over 74 population.

Fall mortality is profoundly selective of the elderly (Figure 2). In the over 74 age group, which reflects the greatest risk, there is considerable cross-national variation by sex, with rates peaking among French and West Germans. In France, West Germany, and the United Kingdom, female rates are approximately 50 percent higher than corresponding male rates. Japan has by far the lowest national rates, and US rates also are relatively low.

Generally, age-specific suicide rates are highest in France, Japan, and West Germany, with the elderly most at risk in all countries (Figure 3). Male rates universally exceed female ones. American females manifest a unique decline in their suicide rate after ages 45–54.

Homicide rates are usually lower than suicide rates, except in the two youngest age groups, where there is a major departure from the norm by the United States because of extremely high homicide rates among adolescents and younger adults of both sexes (Figure 4). In the prime-risk 25–34 age group, the US rate for males ranges from 16 to 29 times other national rates. The US rate for females in that age group, while less than one-fourth that for US males, is still more than triple the second highest national male homicide rate, that of West Germany.

Years of Life Lost

Motor vehicular, suicide, and fall YLL rates are invariably much greater for males than females (Table 2). This finding is repeated with US homicide YLL rates, which for each sex marginally surpass corresponding suicide rates, and dwarf other national homicide YLL rates. Suicide produces the highest sex- and cause-specific YLL rates in Japan; elsewhere it is motor vehicle crashes. Male suicide YLL rates are similar in the United States, France, Japan, and West Germany, and are at least double the British rate. Female suicide YLL rates are highest in France, Japan and West

Germany, and approach the British rate for males. Fall YLL rates are consistently small by sex and across countries.

Discussion

Focusing on 1980 motor vehicle crash, fall, suicide, and homicide data, this research has pointed to substantial differences in the injury mortality profiles of the United States and four other major Western bloc countries: France, Japan, the United Kingdom, and West Germany. Motor vehicle crashes are the predominant cause of injury mortality in the United States, and are also the predominant cause of YLL between ages one and 65 years in all countries under review, except Japan. The sharp peaks in motor vehicular death rates, which are exhibited at ages 15–24 years, have also been observed in many other countries.[16]

A better single indicator of road death risk than an overall population-based mortality rate is number of deaths per motor vehicle distance traveled. In 1980, the United States and the United Kingdom both registered 2.1 road deaths per 100 million vehicle kilometers traveled.[17] The Japanese figure was marginally higher (2.25). In contrast, the French and West German figures were 4.6 and 3.8, respectively. All countries in the study manifested appreciable declines on the exposure measure between 1970 and 1980; from 68 percent for Japan to 30 percent for the United States.[17,18] Similar declines occurred in the overall motor vehicular mortality rates.[13,19] A more protracted downward trend has also been noted for select populations.[20]

A recent US study revealed large inter-county differences in motor vehicle crash mortality rates, which varied inversely with population density and income.[21] The authors speculated that this variation reflected differences in a host of underlying variables, including road quality and design, speed, vehicle type and condition, seat belt use, and access to emergency care. These and other variables, such as alcohol use,[5] vehicle safety design features,[3] access to safer modes of transport, such as trains,[5] and seat belt legislation and related timing, compliance, and enforcement[22] should be integral to analytic epidemiologic research aimed at addressing spatial and temporal variations in the road toll.

*Rates per 100,000 population.

Fall mortality primarily strikes the elderly. Yet geriatric fall deaths are probably markedly undercounted because many of the victims die of complications stemming from the initial injury, and may have a consequential condition coded as their underlying cause of death.[23–25] It is unknown how much of this contributes to the differences observed in this study. There has been a secular decline in the US fall death rate, with a reduction of 35 percent occurring between 1970 and 1980 alone.[5] This trend may be a product of improved medical care, such as hip surgery and earlier mobilization after hip fracture.[4,5] But also unknown is how much of the observed cross-national fall mortality differentials can be explained by quality of care considerations.

Both validation of the WHO cause-of-death data and estimation of the amount of variation in rates attributable to different national coding practices lie outside the scope of this study. However, an explanation was sought for the relatively high percentage of unintentional injury deaths among French males in 1980 that were classified by WHO under the rubric of "all other accidents," and were reflected in the residual injury mortality categories in Tables 1 and 2. The French age mortality distribution for "other" unintentional injuries corresponds to the distribution for motor vehicular injuries, probably due to a frequent tendency by French physicians to write "accident" (coded as unspecified unintentional injury) on the death certificate as the sole external cause descriptor in a fatal motor vehicular trauma case.*

Like motor vehicular death rates, suicide rates vary dramatically by country, age, and sex. The very high rate observed among elderly Japanese females may be a legacy of the unusual degree of sociocultural acceptance that was traditionally accorded suicide in Japan.[26,27] Only the United Kingdom registers lower rates than the United States over most of the age spectrum. American females manifest the lowest national rates among the middle aged and elderly, and the decline in their rates after ages 45–54 is unique. Since American males do not repeat the trend, the finding probably cannot be explained by differential misclassification. However, the stigmatized nature of suicide, coupled with prohibitive clauses in life insurance policies, inevitably raises questions concerning underreporting.[6] Case ascertainment is also affected by definition. While not conclusive, a review of studies on the validity and reliability of official suicide statistics underlines a claim that these data are of sufficiently high quality to justify their use in international epidemiologic comparisons.[28] Cross-national analytic studies, which incor-

porate determinants and correlates that have been identified in recent literature reviews,[29–31] may yield new insights into suicide etiology.

Although homicide accounts for fewer deaths in the United States than either motor vehicle crashes or suicide, US rates are grossly disparate from those in the comparison countries on all three measures utilized in this study. In 1980, handguns featured in an estimated 11,522 US homicides[32]; about half of the total. Handguns were also implicated in fourth-fifths of cases of firearm-related murder and nonnegligent manslaughter,[33] yet constituted only 30 percent of the national civilian firearm stock.[32] The foregoing statistics seem all the more alarming when one considers that in 1980 there were only eight handgun-related homicides in the United Kingdom,[32] which strictly regulates the sale and distribution of firearms, as do France, Japan, and West Germany. The US handgun-related homicide rate was 500 times the British rate, and the overall homicide rate was two-and-a-half times the rate of Northern Ireland,[13] a country in a state of civil war. Moreover, the homicide rate for both sexes rose by 30 percent between 1970 and 1980.[13,19] Results of a recent study suggest that restricting handgun access would be the most effective way to reduce the high US homicide rate.[34] The epidemic of firearm-related homicide (and other violence) warrants unprecedented ameliorative efforts by government agencies at all levels.

Detection of large international differences in disease rates has spawned hypotheses which, following testing, have advanced both understanding of disease etiology and prevention.[35] For example, the determination of such differences in cancer incidence rates[36,37] is credited with stimulating an array of analytic studies indicating that dietary factors have both causative and inhibitory roles in human carcinogenesis.[38] Similar progress could ensue from detection and analysis of international differentials in injury mortality and morbidity.

Determinants of Polychlorinated Biphenyls (PCBs), Polybrominated Biphenyls (PBBs), and Dichlorodiphenyl Trichloroethane (DDT) Levels in the Sera of Young Children

JOSEPH L. JACOBSON, PHD, HAROLD E. B. HUMPHREY, PHD, SANDRA W. JACOBSON, PHD, SUSAN L. SCHANTZ, PHD, MICHAEL D. MULLIN, PHD, AND ROBERT WELCH, MS

Abstract: Serum samples from 285 4-year-old Michigan children were evaluated for levels of 11 environmental contaminants. Polychlorinated biphenyls (PCBs) were found in half the samples tested; polybrominated biphenyls (PBBs) in 13–21 percent; dicholorodiphenyl trichloroethane (DDT), in more than 70 percent. Nursing (Mothers' milk) was the principal source of these exposures. Congener-specific analysis documented the presence of at least one highly toxic PCB congener, 2,3',4,4',5-pentachlorobiphenyl. The data demonstrate the multigenerational impact of female exposure to persistent organic environmental contaminants. (*Am J Public Health* 1989; 79:1401–1404.)

Introduction

Halogenated polycyclic hydrocarbons are among the most ubiquitous and persistent contemporary environmental contaminants. Polychlorinated biphenyls (PCBs), once used in a broad range of industrial products, are found at particularly high concentrations in the fatty tissue of fish feeding in polluted waters, such as Lake Michigan, and in animal products from farms with contaminated silos.[1,2] Polybrominated biphenyls (PBBs), formerly used primarily as flame retardants, were accidentally mixed with cattle feed in Michigan in 1973–76, leading to widespread dairy and meat contamination throughout the state.[3] Dichlorodiphenyl trichloroethane (DDT), developed to control malaria-carrying mosquitoes, became one of the world's most extensively used pesticides in the 1950s and 1960s.[4] Dichlorodiphenyl dichloroethene (DDE) is its most stable and persistent metabolite.

PCBs, PBBs, and DDE are not readily excreted, except by lactation.[5] Placental passage has been documented for PCBs and PBBs,[6–8] although much larger quantities are transferred to the infant postnatally in breast milk due to its high lipid content.[9] A positive relation between duration of nursing and serum PCB level in young children has been reported in three studies, one in Germany[10] and two in Japan.[5,11]

Methods

The study included two cohorts of children evaluated at age 4 years. The "fish exposure cohort" consisted of 236 children recruited in 1980–81 when 8,482 women delivering infants in four western Michigan hospitals were surveyed regarding their consumption of Lake Michigan sport fish.[12] "Contaminated fish consumption" was defined as the sum of annual Lake Michigan fish consumption, weighted by the PCB content of the species consumed, in the present or past, whichever was greater.[13] All women consuming at least 11.8 kg over a six-year period (4.0 percent of those interviewed) were invited to participate in the study. A small proportion (4.6 percent) of those who did not consume these fish were also recruited and constituted 22.7 percent of the final sample. Of those assessed as infants, 75.4 percent were seen again in the present study. The children evaluated at age 4 did not differ from those not retained in the sample in terms of cord and maternal serum PCB levels but were somewhat higher in socioeconomic status (SES) and maternal fish consumption and milk PCB levels.[14]

The "farm exposure" cohort consisted of 87 children who had not previously been assessed as infants. Their families were enrolled in long-term studies of exposure to PBB or PCB contaminated farm products conducted by the Michigan Department of Public Health. The PBB families had lived on or received food from quarantined farms;[15] the PCB families had eaten milk and meat from farms whose animals consumed silage contaminated with PCBs.[16]

Information regarding family SES and residence, maternal age, weeks of breast feeding, maternal contaminated fish consumption during and before pregnancy, and child's contaminated fish consumption during the previous year was obtained by maternal interview at the four-year assessment. When compared with similar information obtained from the fish exposure cohort during infancy, test-retest reliabilities (Pearson r) ranged from 0.68 for maternal fish consumption to 0.99 for maternal age (median = 0.81).[14] The four-year maternal fish consumption report was also validated in relation to maternal serum PCB level obtained at delivery ($r = 0.37$, $P = 0.000$). Venous blood was obtained from 285 of the 323 children. Specimens were obtained from 250 children at age 4, 35 children at age 5. Levels of PCBs, PBBs, DDT, and lead did not differ significantly at the two ages.

Total serum PCB level was evaluated by the Michigan Department of Public Health by packed column electron capture gas chromatography, adapting the Webb-McCall method[17] to a computer data system, in which Aroclors 1016 and 1260 were used as reference standards.[18] Quantitation was also provided for PBBs, Total DDT (p,p'-DDT + p,p'-DDE), hexachlorobenzene, beta HCB, oxychlordane, heptachlor epoxide, trans-nonachlor, and mirex. The same laboratory had previously provided data on PCB and PBB levels in umbilical cord serum, maternal serum collected two to three days after delivery, and maternal milk for the fish

TABLE 1—Environmental Contaminants Found in the Sera of Young Children

	Total N	Children with Trace Levels (1 ng/mL) or Greater			
		%	Mean	s.d.	Range
PCBs					
Fish exposure	205	52.2	4.18	3.29	1.00–19.40
Farm exposure	80	48.8	4.82	4.81	1.00–23.30
PBBs					
Fish exposure	205	12.7	2.44	1.50	1.00–6.40
Farm exposure	80	21.3	2.95	2.66	1.00–9.50
Total DDT					
Fish exposure	202	69.8	4.36	3.87	1.00–21.40
Farm exposure	79	77.2	4.24	4.47	1.00–143.20*
Lead†					
Fish exposure	194	—	0.30	0.16	0–1.01
Farm exposure	77	—	0.32	0.17	0.10–1.21

Means are ng/mL, except for lead μmol/L. The laboratory detection limit for PBBs and DDT is 1 ng/mL; for PCBs, 3 ng/mL. 26.3% of the fish exposure children and 23.8% of the farm exposure children had PCB levels of 3 ng/mL or greater.

*Two outliers (143.2 and 73.4) are recoded to 15 for mean and s.d. calculation, as recommended by Winer.

†Mean, s.d., and range are based on all cases tested.

exposure cohort using the same analytic method.[13] Quality control has been maintained consistently since 1979 in interlaboratory comparisons following protocols established by the Centers for Disease Control and the Environmental Protection Agency. The four-year blood samples were also analyzed for lead by atomic absorption spectrophotometry using the Delves cup method.

With the exception of the breast milk PCB and four-year blood lead levels, all of the exposure measures were positively skewed (skew > 2.5) and normalized by means of log X + 1 transformation. Means and standard deviations are reported in terms of the original distributions; the log transforms were used in the correlation and regression analyses. Child's contaminated fish consumption was measured in terms of current annual kg consumed (log X + 1) with species weighted to reflect degree of PCB contamination.[13] Weeks of nursing was transformed by recoding seven values greater than 3 standard deviations above the mean to 1 point greater than the highest observed value, as recommended by Winer.[19]

Results

PCBs were detected in about half of the 4-year-olds tested; PBBs, in relatively few samples; and DDT, though banned for many years, in a large majority of the children (Table 1). Although the mothers in the fish exposure cohort had eaten more Lake Michigan fish before and during pregnancy than their farm exposure counterparts, 7.6 kg/yr versus 1.2 kg/yr, PCB and DDT levels were similar in the two groups of children. PBBs, which had been a specific contamination problem on many of the farms, were somewhat more prevalent in the farm exposure cohort.

DDE averaged 89.0 percent of the total DDT in the children's sera, which is similar to the 86.7 percent reported for a more highly exposed, predominantly Black, rural sample in the early 1980s.[20] Except for hexachlorobenzene, which was present at low levels (< 2.0 ng/mL) in three cases, none of the other organochlorine pesticides tested were detected in the four-year samples. Lead levels were generally low, although 11 children had levels between 0.72 and 1.21 μmol/L.

The relation of several hypothesized determinants to four-year body burden is shown in Table 2. All predictors with zero-order correlations significant at $P < 0.10$ were also included in multiple regression analyses, which adjusted statistically for confounding among the predictors. While cord serum level was unrelated to PCB body burden at age 4 ($P = 0.615$), maternal milk PCB level and weeks of breastfeeding jointly explained 59.7 percent of the variance in four-year PCB level ($P = 0.000$). In the absence of nursing, the children's body burdens diminished with time as growth reduced the proportion of the original *in utero* dose (Table 3). Prolonged breastfeeding, by contrast, was associated with substantial increases in PCB burden. Where maternal milk PCB level exceeded 1000 ng/mL, each additional week of nursing was associated with a 0.19 ± 0.03* ng/mL increase in the child's four-year serum PCB level. Where maternal milk level was less than 600 ng/mL, the increase associated with each week of nursing was 0.09 ± 0.02 ng/mL. Socioeconomic status (SES) and maternal age were not significant predictors of four-year PCB serum level after adjustment for nursing exposure in the regression analysis. The SES effect was attributable to the fact that higher SES mothers nursed for longer periods; the maternal age correlation, to higher PCB levels in the milk of older mothers.

Maternal milk PBB level and weeks of nursing jointly

*Unstandardized regression coefficient ± s.e. from a univariate regression of four-year serum PCB level (prior to log transformation) on weeks of nursing

TABLE 2—Effects of Pre- and Postnatal Predictors on Four-year Serum Contaminant Levels

	N	PCBs		PBBs		DDT		Lead
		Unadjusted	Adjusted	Unadjusted	Adjusted	Unadjusted	Adjusted	Unadjusted
Cord serum level	126	0.05	—	0.29	0.34	—	—	—
Maternal milk level	107	0.29	0.33	0.39	0.31	—	—	—
Weeks of breastfeeding	285	0.66	0.70	0.42	0.42	0.61	0.56	−0.11
Socioeconomic status	285	0.26	0.07	0.23	0.09	0.29	0.08	−0.21
Maternal age	285	0.15	0.01	0.09	—	0.26	0.11	−0.15
Rural residence*	285	0.01	—	0.02	—	0.12	0.13	0.03
Child's fish consumption	285	0.08	—	0.02	—	0.03	—	0.01
Multiple R		—	0.78	—	0.65	—	0.64	—

Unadjusted values are zero-order Pearson correlation coefficients. Adjusted values are standardized regression coefficients from analyses in which each contaminant was examined in relation to the set of predictors for which values are shown. All PCB, PBB, and DDT values below the laboratory's detection limits were recoded to 0 before being subjected to correlational and regression analysis.

*Coded 0 for urban or suburban, 1 for rural.

TABLE 3—Comparisons of Cord and Four-year Serum PCB Levels in Relation to Duration of Breastfeeding

Months of Breastfeeding	N	Cord Serum PCB level	Four-year Serum PCB level
0.0–2.9	66	2.8	0.6
3.0–5.9	17	2.2	2.3
6.0–11.9	30	2.6	4.4
12.0+	13	2.1	5.5

Means are ng/mL.

explained 31.5 percent of the variance in four-year serum PBB level (P = 0.000). Although four-year PBB body burden was correlated with cord serum level as well, inspection of a scatterplot relating the breast milk and four-year PBB levels suggested that the relation between these variables was curvilinear. When a quadratic term for milk level was added to the regression, the multiple R increased significantly to 0.69, and the standardized regression coefficient for cord serum PBB level was no longer significant, $\beta = 0.10$, P = 0.384. Moreover, a case by case examination of the data on which the PBB regression was based indicated that all the children with detectable four-year serum PBB levels had been nursed for at least four months.

Although no data were available on breast milk DDT levels, duration of nursing explained 36.8 percent of the variance in four-year serum DDT level (P = 0.000). DDT levels were also higher in children in rural areas and in the children of older mothers, even after adjustment for weeks of nursing (Ps = 0.007 and 0.032, respectively). Because the total DDT in these children consisted primarily of DDE, the correlation and regression coefficients for these predictors in relation to DDE were virtually identical to those shown for total DDT. No regression was computed for lead because the magnitude of its relations with these predictors was small.

The Webb-McCall isomer identification method records chromatographic elution peaks, each of which is comprised of one or more specific PCB congeners (Figure 1). Peaks 203, 232/244, 332, and 372 were statistically more prevalent in the farm exposure cohort, suggesting that the farm children may

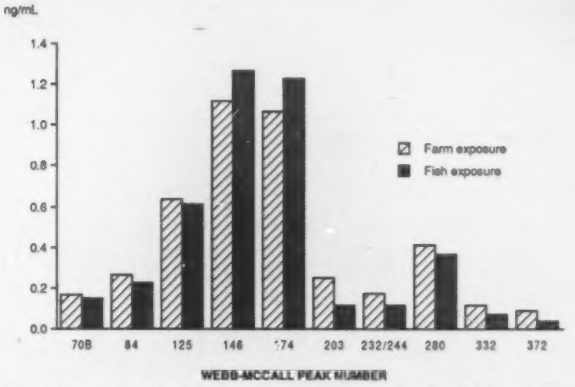

FIGURE 1—Webb-McCall chromatographic elution peak values by exposure cohort.

have been exposed to sources of PCBs to which the fish cohort children were not exposed. Despite these differences, the overall pattern of elution peaks was highly similar in the two cohorts and closely matched the pattern found by Humphrey[21] in adults and regular fish eaters. Although many different PCB mixtures have been deposited in the environment,[22] these data confirm that certain congeners are preferentially accumulated in both adults and children.

Serum extracts from 20 children with PCB serum levels in excess of 3.0 ng/mL were pooled into two composite samples—one for the boys (N = 9); the other for the girls (N = 11)—and analyzed at the US Environmental Protection Agency Large Lakes Research Station at Grosse Ile, Michigan, by means of capillary column gas chromatography.[23] The type and concentration of PCB congeners found in the two pooled samples were highly consistent (Table 4), making it unlikely that the pattern observed was determined by one or two aberrant children. The most prevalent congeners, Nos. 153, 138, 180, and 118, were also among the most prevalent in human milk and serum samples evaluated in prior studies.[25–29] No. 118, a constituent of Webb-McCall Peak 125 (Figure 1), is a mono-*ortho* analog of the highly toxic

coplanar PCB congeners, which elicit effects resembling those caused by 2,3,7,8-TCDD. This congener, which has also been detected at relatively high concentrations in human milk in the US,[25,26] Germany,[27] and Japan,[28] is likely to provide a major contribution to the overall toxicity of these children's PCB exposure.[26,30]

Discussion

The present data implicate nursing as the principal source of PCB and PBB exposure in these children and a significant source of DDT exposure as well. Although prenatal PCB exposure has been shown to affect physical and behavioral development,[12,31,32] the quantity transferred *in utero* is apparently too small to detect in serum by age 4 years. In contrast to transplacental exposure, developmental deficits have not been linked to postnatal nursing exposure in North American children,[33,34] although dermatological effects from nursing have been documented in the infants of occupationally exposed women in Japan.[35]

Postnatal exposure to the halogenated hydrocarbon contaminants was greater for higher SES children, because their mothers tended to breastfeed for longer periods. Postnatal fish consumption by the child had little effect on PCB body burden, because most children ate less than one fish meal per year. While virtually all of the children with PCB levels of 3.0 ng/mL or greater had breastfed for at least six weeks, one child who had nursed for only two weeks but had eaten 84 contaminated fish meals in the previous year also had an elevated PCB body burden at age 4.

ACKNOWLEDGMENTS

This research was funded by National Institute of Environmental Health Sciences Grant R01-ES03256, Health and Human Services Corporative Agreement U37/CCU500392, and a research enhancement grant from the Wayne State University Institute of Chemical Toxicology. The collection and analyses of the infant data were funded by Grant CR80852010 from the US Environmental Protection Agency (Greta G. Fein, Principal Investigator). We wish to thank Greta G. Fein and Pamela M. Schwartz, who collaborated on the infant phase of this research, Marvin Budd, who coordinated the specimen collection, and Robin L. Billings, who assisted in the analyses of the data presented here.

Commentary

Fluoridation Referendum in La Crosse, Wisconsin: Contributing Factors to Success

RHYS B. JONES, DDS, MS, DOUGLAS N. MORMANN, MS, AND TIMOTHY B. DURTSCHE, DDS

Abstract: Residents of La Crosse, Wisconsin approved a public referendum in favor of water fluoridation on April 5, 1988. The vote, 57 percent supportive, culminated a two-year community effort. Three public referenda had been defeated in the past. Contributing to the success of this recent campaign were: broad-based community support led by a 34-member Citizens for Better Dental Health in La Crosse Committee; American Dental Association/Wisconsin Division of Health/US Public Health Service consultation and support; knowledgeable and supportive press coverage; the timing of the ballot to coincide with the Wisconsin Presidential Primary; and local chiropractic support to offset chiropractic anti-fluoridation leadership. La Crosse, population 50,000, was the largest fluoride-deficient community in a nine-state upper Midwest area. (*Am J Public Health* 1989; 79:1405–1408.)

Introduction

Water fluoridation, the purposeful supplementation of naturally occurring fluoride to optimal levels for the prevention of dental caries, is one of the most successful public health measures in history.[1–3] Nevertheless, despite over 40 years documentation of safety, efficacy, cost-effectiveness, and practicality, and the unqualified endorsements of every major health organization, water fluoridation is far from universal in the United States. At the present time, approximately 63 percent of the US citizens have access to community drinking water containing dentally significant levels of fluoride (0.7 ppm).*

From a public health perspective, centralized decision-making by local health administrations affords the best opportunity for fluoridation implementation in the 42 states which have no legislatively mandated fluoridation.[4,5] Unfortunately, decisions on fluoridation in many communities are made in a highly charged political arena.[6,7] A number of fluoride-deficient communities in the US have failed to fluoridate because of initiative defeat in public referenda.[8,9] Fluoridation remains one of the few, if not the only, public health measures to be put to the vote of the public. Of the 150 referenda recorded by the Dental Disease Prevention Activity, Centers for Disease Control from 1980 through 1988, 64 percent (96) ended in failure for fluoridation proponents. Oftentimes proponents are ill-prepared for the political nature of a fluoridation campaign. By contrast, over the same time period, in 258 communities where the decision was left to administration (city councils or health boards), 77 percent (199) implemented fluoridation* (Table 1).

The purpose of this discussion is to outline key contributing factors in a recently successful fluoridation initiative in La Crosse, Wisconsin. A 20-month community effort resulted in a 57 percent positive vote for fluoridation. These contributing factors to success may be applicable to fluoridation strategies in other fluoride-deficient communities where the issue is decided by public referendum.

La Crosse Historical Perspective

La Crosse, 50,000 population, was the largest fluoride-deficient community (0.1 ppm) in a nine-state upper Midwest region. Although 93 percent of Wisconsin residents on public water supplies have optimally fluoridated water, La Crosse has a long history of antifluoridation obstructionism. On three occasions, voters rejected fluoridation in public referenda despite widespread support from health professional organizations. In 1953, by council action, the city fluoridated for three months until antifluoridation forces led by area chiropractors pressured officials to reconsider. Soon after, a first referendum failed with only 18 percent positive vote. The fluoridation equipment was disconnected and sold.

A second referendum failed in 1967 with 43 percent support; a third in 1969 gained only 29 percent support. Antifluoridation influence continued in the 1970s and 1980s driven by a prominent local chiropractor whose family had led the fight against fluoridation for over 30 years. Tactics used by La Crosse anti-fluoridationists through the years copied national anti-strategies capitalizing on the concerns of

society at the time. Fluoridation was alleged to be a Communist plot in the 1950s, a cancer causing "toxic waste" and "poison" in the 1960s and 1970s, and by the 1980s linked to aging, Alzheimer's disease, AIDS and "freedom of choice."

Renewed Fluoridation Initiative

La Crosse community leaders renewed fluoridation efforts in 1986 in response to a perception that a majority of a new city council would be supportive. A local committee was formed led by a representative of the La Crosse District Dental Society and the county public health department director. Efforts were directed toward convincing an 18-member city council to implement fluoridation without public referendum by convincing councillors of the health benefits of fluoridation as well as demonstrating public support for the initiative. Community support was strong through four public hearings and led to a June 1987 city council 10 to 8 vote for fluoridation, the first positive vote in 34 years. Despite the positive vote, the council delayed funding for 60 days thus allowing opponents the opportunity to petition for public referendum. This allowed fluoridation opponents to obtain the 3,000 signatures necessary to force a referendum. The pro-fluoridation majority of the council set the date for the referendum at the next major election, April 5, 1988, the Wisconsin Presidential Primary, rather than at an earlier special election date for a school bond. The wording of the ballot, an important component of successful fluoridation referenda, read in a straightforward and simple manner as follows: "Should the City of La Crosse fluoridate its water supply?"

Factors Contributing to Success

When compared to the previous defeats, the following five factors could be identified:

Broad-Based Community Support

A broad support base is necessary to assure success once a fluoridation issue is politicized.[4,8] Soon after the establishment of the referendum date, the original pro-fluoridation committee formed a campaign organization, "Citizens for Better Dental Health in La Crosse." The organization included representatives from health professional associations, the public health sector, hospitals, business and industry, labor, university, and civic and community organizations. The Citizens for Better Dental Health met twice a month for five months preceding the April referendum, planning and implementing an educational and political campaign for fluoridation. A subcommittee structure centered on a number of campaign tasks. The agenda reflected a strong local commitment with knowledgeable and credible spokespersons. Strategy for political success included: no debates or public forums that give antifluoridationists credibility; no distractions from a central theme of better health; less time on technical merits and more time on targeting groups of voters, identifying supporters and encouraging their turnout (see Appendix for further details).

Scientific Press Coverage

Scientific evaluation of the fluoridation issues by an influential press was an asset to the fluoridation initiative. Print media coverage in La Crosse was extensive and well-researched. The *La Crosse Tribune*, with a circulation of 40,000, is the largest newspaper in southwest Wisconsin. The fluoridation issue provoked much public debate as evidenced by 142 letters-to-the-editor (pro and anti) published by the newspaper during the course of the initiative.

It was of great benefit that the health reporter for the *Tribune* (a college chemistry major) was knowledgeable in the history, science, and efficacy of water fluoridation. This resulted in positive and informative health reporting on the issue. Headlines reflected positive leads such as "Fluoride—History Shows No Reason for Controversy—What's the Fuss?" Supportive editorials as one entitled "Let's Get Beyond the Pseudo-Science" appeared throughout the campaign. When spurious newspaper advertisements were run by opponents, follow-up stories refuted erroneous claims. For example, an antifluoridation paid advertisement was entitled "Fluoridation Causes Corrosion of Pipes. Vote No to Fluoridation." The following day an article appeared discrediting the corrosion charge through interviews with the La Crosse Water Utility manager and Centers for Disease Control officials in Atlanta, GA and citing research and fluoridation endorsements from the National Institutes of Health, Bell Laboratories, the American Water Works Association, and the National Association of Corrosion Engineers. The decision of the local press to forego sensationalizing the issue in deference to accurately educating the public was a critical factor toward success.

ADA and Governmental Agency Support

The La Crosse committee utilized a number of sources for consultative support. The American Dental Association (ADA) provided technical and financial support. National experts gave council testimony and committee consultation through ADA sponsorship. The ADA's Water Fluoridation Campaign Package and other written and audio/visual materials were provided. ADA letters of endorsement were sent to the city and the *La Crosse Tribune*.

The Wisconsin Division of Health through the State Dental Director's office provided technical assistance throughout the course of the initiative. Literature reviews, strategy development, and analyses of other fluoridation referenda were utilized by the committee. A state cost-sharing grant for fluoridation equipment was available to the community.

The community also used the services of the US Public Health Service. Consultation and letters of support were utilized through the Dental Disease Prevention Activity of Centers for Disease Control in Atlanta and the US Surgeon General's Office, Washington, DC. The most notable letter of support was from US Surgeon General C. Everett Koop. Dr. Koop's letter to the *La Crosse Tribune*, published just prior to the referendum date, applauded the fluoridation initiative. It was accompanied by a front page article entitled "Surgeon General to Voters: Fluoridate."

Wisconsin Presidential Primary

If fluoridation approval is subject to public referendum, the timing of the ballot is an important factor for success. It is generally perceived that fluoridation referenda should coincide with primary or general elections that promise the largest voter turnout ensuring a broader community participation rather than in smaller special issues elections.[8] The La Crosse referendum was set to coincide with the 1988 Wisconsin Presidential Primary. Fortunately, the Wisconsin Primary in the spring of 1988 was of national significance. Presidential candidates George Bush, Michael Dukakis, Jesse Jackson, and Albert Gore all campaigned in the La Crosse area. Voter interest and turnout was high. A pre-election *La Crosse Tribune*-sponsored poll was conducted by the political science department of the University of Wisconsin-La Crosse found 58 percent of city voters in favor of fluoridation,

27 percent opposed, and 15 percent undecided (Table 2). Support for fluoridation was highest among the better educated and younger voters. Among college graduates, 71 percent favored fluoridation while 62 percent of those with some college and 37 percent of those who never attended college supported the issue. Only 41 percent of citizens over age 65 supported fluoridation. Post-election analysis of voter turnout identified high participation of younger voters who had been targeted by the profluoridation organization.

Chiropractic Support

Chiropractors were among early opponents to fluoridation in the United States. Some continue to oppose fluoridation in many areas as being an infringement of personal freedom, a dictate of organized medicine, and incompatible with chiropractic nutritional philosophy.[10,11] More recently, some chiropractors are active as proponents to fluoridation and several chiropractic organizations are reaching out to the scientific community by endorsing the scientific principles of public health.[12]

For the first time in La Crosse, chiropractors were on both sides of the fluoridation issue. A few chiropractors presented supportive public testimony and actively campaigned for fluoridation. The controversy in the local chiropractic community gained statewide attention, often overshadowing other issues, and may have contributed to a loss of credibility for the primary chiropractic opponents to fluoridation. Sentiments of a proponent chiropractor are reflected in this statement which appeared in a Madison, Wisconsin newspaper: "Chiropractors are interested in public health. Fluoridation is an extremely important issue. Chiropractors have a drugless healing profession, but the feeling that fluoridation is medication is absurd. It is an essential nutrient that naturally occurs."[13]

Summary

The majority of public referenda on water fluoridation in US communities are defeated at the polls. A "confusion hypothesis" has been formulated to explain such a continuing negative voter response to fluoridation initiatives.[7,10,14] Voters are often confused by apparent contradictory information from proponents and opponents of fluoridation. The general public, unable to evaluate highly technical information, credits antifluoridationists as scientific spokespersons. The scientific community has not been all that effective in helping the public understand who is an expert and who is not.[7]

In La Crosse, the Citizens for Better Dental Health were able to overcome a long history of antifluoridation influences through educational and political strategies. Broad-based community support, consultative assistance, scientific press coverage, the timing of the ballot, and chiropractic support all contributed to the success of the initiative.

APPENDIX A
La Crosse Fluoridation Campaign Activities

Citizens for Better Dental Health in La Crosse

Committee with broad-based community coalition.
Endorsement by physicians and dentists.
Endorsement by civic and health organizations (American Cancer Society, local hospitals, Committee on Aging, Chamber of Commerce, AFL/CIO).

Campaign Headquarters

Placed in a highly visible downtown center location.
Opened headquarters with a press conference.
Coordinated campaign activities.
Created headquarters' theme: "Come in and take the taste test" (to counter an anti misinformation campaign regarding the taste of fluoridated water).

Speakers' Bureau

Provided knowledgeable public speakers in support of fluoridation.
Assigned speakers to civic organizations, labor groups, parent associations, and others.

Media Strategies

Identified media contact expert interviewees.
Organized positive and timely letters-to-the-editor.
Developed newspaper and radio advertisements.

Campaign Literature

Designed informational brochures for direct mail distribution, door-to-door literature drop, speaking engagements, and community locations (malls, businesses, professional offices).
Printed and distributed yard and window signs for homes, schools, and businesses.

Fund Raising

Solicited $10,000 in donations from civic/professional organizations, foundations, business, and individuals.
Print design and media production donated by a major local industry.

Getting Out the Vote

Identified and registered fluoridation supporters.
Organized special initiatives i.e., schools (parent-to-parent contact) and university (student voter registration drive).
Arranged car-pooling assistance to the polls.
Assisted with absentee ballots.
Utilized 750 volunteers in the campaign.

ACKNOWLEDGMENT

This paper was presented at the 51st annual meeting of the American Association of Public Health Dentistry in Washington, DC, October 1988.

Alfred Yankauer, MD, MPH, to Retire as Journal Editor; Search Committee Actively Seeking New Editor

Alfred Yankauer, MD, MPH, has indicated he plans to retire as editor of the *American Journal of Public Health* next year, effective July 1 1990. The announcement of his retirement appeared in the September issue of *The Nation's Health*, along with information about the newly appointed search committee—which is soliciting nominations for his replacement—and a list of the qualifications for the position of editor.

Dr. Yankauer will complete his 15th year as editor before stepping down next summer; his service spans the period July 1975–July 1990. Only two editors have served longer: George Rosen, MD, who preceded Dr. Yankauer, served for 16 1/2 years (August 1957–December 1973), and Mazÿck P. Ravenel, MD, served 16 years as editor (January 1925–December 1940) and was then named emeritus editor in 1941. All three editors were members of the editorial board or the editorial committee before being named editor. Fourth in line for length of service was C.-E. A. Winslow, DrPH, who held the position for 10 1/2 years (April 1944–November 1954) before retiring for health reasons.

Since the *American Journal of Public Health* was established in 1911, only 11 persons have occupied the position of editor. The four editors named above filled the role collectively for 58 years, while seven others shared the honor a total of 22 years.

In announcing his desire to retire, Dr. Yankauer stated that, "It was a decision not lightly made," because he said he has both enjoyed and learned from the experience. "However, at this point in my life, there are other things that I want and need to do," he added.

Each of the 11 editors of the Journal served that post with distinction and made a lasting impact on the Journal, its readers, the public health profession, and the health of the public. Under their respective leadership over eight decades, the Journal has grown in stature and scientific credibility. Its reputation for accuracy, relevance, and timeliness in the field of peer-reviewed professional journals has been maintained and enhanced by their devotion to its content and to its objectives.

Over the years, the Journal's table of contents has reflected current thinking about the health status of mankind and what needs to be done to improve it. The Journal has been a repository throughout the 20th century for articles, studies, and evaluations authored by hundreds of dedicated health professionals.

As the Editor Search Committee carries out its difficult task of identifying potential candidates for the position of Journal editor, they will be seeking an individual with broad public health interests, a strong historical perspective, an abiding concern for the health and well-being of others, and exceptional vision.

Nominations for Journal editor should be submitted as soon as possible, so that the search committee can complete its deliberations by the end of this year. Names of potential candidates, along with support materials, should be sent to the Editor Search Committee, c/o Executive Director's Office, American Public Health Association, 1015 15th Street, NW, Washington, DC 20005. A list of the criteria for selection of an editor appeared in the September issue of *The Nation's Health*, or may be obtained on request to APHA headquarters. Tel: (202)789-5600.

Cocaine and Heroin Dependence Compared: Evidence from an Epidemiologic Field Survey

JAMES C. ANTHONY, PHD, AND KENNETH R. PETRONIS, MS

Abstract: Analyzing self-report interview data from a multi-site collaborative study of mental disorders in the community, we examined suspected differences between 611 cocaine users and 126 heroin users in relation to indicators of drug dependence. Cocaine users were less likely to report dependence-related problems as compared to heroin users. These epidemiologic sample data underscore concerns about the generalizability of published clinical sample data on self-reported cocaine dependence. (*Am J Public Health* 1989; 79:1409–1410.)

Introduction

Recently Hasin, *et al*, described 75 cocaine users and 67 heroin users, drawn from 308 patients in an alcohol treatment unit. Answering standardized drug questions in the Diagnostic Interview Schedule (DIS), cocaine users reported having felt dependent on cocaine just as frequently as heroin users reported having felt dependent on heroin. Further, cocaine users and heroin users differed little on other reported dependence indicators (withdrawal, loss of control, tolerance). While citing this as evidence that cocaine has dependence-generating potential comparable to that of heroin, the authors cautioned that drug users in treatment might have had different experiences than users in the general population.[1]

Previously, our research group reported on cocaine use and cocaine problems in the community, based on DIS data from the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Program.[2] For this paper we re-analyzed the data for direct comparison to the data reported by Hasin.[1]

Methods

Collaborators at four ECA sites obtained interviews with 13,538 subjects between 1981 and 1984 after drawing probability samples of adult household residents in Baltimore, Maryland, St. Louis, Missouri, Durham, North Carolina, and Los Angeles, California. To assess psychiatric conditions, including drug-related problems, staff administered the DIS soon after sampling. The mean participation rate was 76 percent (range 68–79 percent). (New Haven, Connecticut ECA data sets do not include drug variables needed for this analysis.)

Hasin, *et al*, describe psychometric characteristics of the DIS.[1] Elsewhere, we have published data from a DIS validity study,[3] descriptions of DIS drug data,[2,4,5] and reports on sampling and other methods used in the ECA program.[6,7]

Analyses for this paper follow specifications of the clinical sample paper. The results shown are unweighted characteristics of the sample; use of sampling weights increases differences between the two studies.

Results

Among ECA subjects, 57 reported having used heroin every day for at least two weeks ("daily heroin use"); 69 reported using heroin at least six times, but never daily for two weeks. An additional 611 subjects reported having used cocaine (but not heroin) at least six times; 69 of these users reported having used cocaine every day for at least two weeks ("daily cocaine use"). These users were sociodemographically similar to those in the clinical sample (data available upon request to authors). Whereas alcohol disorders affected virtually all of the clinical sample, in the ECA sample they affected only 35 percent of the non-daily cocaine users, 52 percent of the daily cocaine users, and about 60 percent of the heroin users.

Table 1 shows for daily and non-daily cocaine and heroin users in the ECA sample the proportion who reported feeling dependent on cocaine, unsuccessfully cutting down on cocaine use, cocaine tolerance, or cocaine withdrawal.

ECA cocaine users were less likely to report cocaine-related problems than users in Hasin's study: 2.6 percent of ECA non-daily users and 22.1 percent of ECA daily users reported feeling dependent on cocaine compared to 14 percent and 79 percent, respectively, in Hasin's study; for unsuccessfully attempting to cut down on cocaine use, corresponding figures were 2.4 percent and 11.6 percent vs 14 percent and 64 percent; for tolerance, 7.7 percent and 42.0 percent vs 26 percent and 64 percent. Finally, 1.0 percent of ECA non-daily users and 13.0 percent of daily users reported feeling withdrawal sickness upon stopping or cutting down on cocaine use, as compared to 19 percent and 76 percent in Hasin's sample.

Our sample and Hasin's sample also differed in relation to heroin experience, although not as markedly as with cocaine. Among ECA non-daily and daily heroin users, respectively, 7.2 percent and 78.6 percent reported having felt dependent on heroin, as compared to 11 percent and 85 percent in Hasin's study. For loss of control, comparable figures were 1.5 percent and 40 percent vs 16 percent and 63 percent; for heroin tolerance, 12 percent and 68.4 percent vs

TABLE 1—Dependence Indicators for Cocaine and Heroin, by Patterns of Use, based on Data from the Epidemiologic Catchment Area Surveys in Baltimore, St. Louis, Durham, and Los Angeles, 1980–84

	Cocaine				Heroin			
	Group 1 (N = 542 6+ times, Never daily for 2 weeks)		Group 2 (N = 69 Daily 2 weeks or longer)		Group 3 (N = 69 6+ times, Never daily for 2 weeks)		Group 4 (N = 57 Daily 2 weeks or longer)	
Dependence Indicators	%	n	%	n	%	n	%	n
Ever felt dependent on drug	2.6 (4 missing)	14	22.1 (1 missing)	15	7.2	5	78.6 (1 missing)	44
Ever unable to cut down on amount used	2.4	13	11.6	8	1.5	1	40.4	23
Ever felt tolerance to drug's effects	7.7 (7 missing)	41	42.0	29	11.8 (1 missing)	8	68.4	39
Ever experienced withdrawal	0.9 (3 missing)	5	13.0	9	10.1	7	75.4	43

Differences in proportions between groups 1 vs 3 and groups 2 vs 4 were as follows (95% confidence limits):

	Group 1 vs. Group 3	Group 2 vs. Group 4
Felt dependent	−4.6 (−10.9, 1.6)	−56.5 (−71.1, −41.9)
Unable to cut down	0.9 (−2.2, 4.1)	−28.8 (−43.6, −14.0)
Tolerance	−4.1 (−12.1, 3.9)	−26.4 (−43.2, −9.6)
Withdrawal	−9.2 (−16.4, −2.1)	−62.4 (−76.1, −48.7)

26 percent and 85 percent; for heroin withdrawal experience, 10 percent and 75 percent vs 21 percent and 83 percent.

Unlike the cases reported by Hasin, ECA daily cocaine users were much less likely than daily heroin users to report problems, as shown by negative signs on the upper confidence limits for each estimated difference (Table 1).

Discussion

This epidemiologic study's evidence calls into question the generalizability of results from the prior study of patients in an alcohol treatment unit. Responding to identical self-report interview questions, smaller proportions of cocaine users in the community sample reported dependence-related problems. Moreover, daily cocaine users in this sample were substantially less likely to report dependence-related problems, as compared to daily heroin users.

One hypothesis about these differences in study results is that drug users in alcohol treatment are more willing to give a complete report about drug-related problems. Alternatively, alcoholism or admission to alcoholism treatment may index especially intensive patterns of drug use or increased risk for problems with other drugs, especially cocaine. If so, clinical samples are unreliable sources of data on the frequency of drug hazards in the community, as discussed elsewhere.[1,2]

Putting these results in perspective, there is strong laboratory evidence on reinforcing properties of cocaine. Across several species, cocaine is self-administered repetitively in patterns that fulfill broadly accepted case definitions for drug dependence.[8,9] These interview data do not contradict that evidence.

ACKNOWLEDGMENTS

This research was supported in part by grants from the National Institute on Drug Abuse (DA03992) and the Academic Data Processing Center of the Johns Hopkins University School of Hygiene and Public Health. Principal investigators for the original ECA data gathering grant awards were M. Kramer (Baltimore), J. K. Myers (New Haven), L. N. Robins (St. Louis), D. Blazer (Durham), R. Hough and M. Karno (Los Angeles). During data gathering, principal collaborators at NIMH were D.A. Regier, B. Z. Locke, and W. W. Eaton.

Improving Patient Comprehension of Literature on Smoking

CATHY D. MEADE, RN, PHD, JAMES C. BYRD, MD, MPH, AND MARTHA LEE, PHD

Abstract: This study was designed to determine if simplification of smoking literature improved patient comprehension. Subjects (N = 129) were randomized in three groups: to receive no smoking booklet, receive one written at the 5th grade, or the 10th grade reading level. Subjects receiving the 5th grade booklet showed 13 percent better comprehension than those receiving the 10th grade booklet, and 18 percent better than the controls. Comprehension of written smoking materials can be improved by adjustment of the reading grade level. (*Am J Public Health* 1989; 79:1411–1412.)

Introduction

Printed materials on smoking are commonly distributed to patients in hospitals, clinics, or smoking cessation programs.[1–5] Such materials communicate, reinforce, and extend the educational message presented verbally by practitioners.[6,7]

Studies indicate that the median level of most patient educational materials is grade 10, a reading level often greater than the majority of its intended target population.[8–13] In a review of 49 educational brochures specific to smoking, the median reading level was 10.5 while the median reading level of patients (N = 258) was grade 6.[14]

Comprehension and acceptability of written materials should improve if materials are made easier to read; however, few data are available to either support or refute this idea. Reported studies have lacked control groups, pretest measures,[15–17] randomization, or description of reliability of the instruments.[15–16] No study reported has yet evaluated the effect of simplification of smoking literature on patient comprehension. We report here such a study.

Methods

Two booklets on smoking, each entitled "Quit Smoking and Feel Good," were developed based on a review of the smoking literature and a panel of experts. The booklets mirrored each other in color, design, writing style, print type, length, and organization. The Minnesota Interactive Readability Approximation Microcomputer Program was used to adjust the readability level of one booklet to grade 5 and the other to grade 10.[18]

To evaluate smoking knowledge and recall, 24 questions were developed by the investigators with a panel of experts based upon the content of the booklets. The reliability of the test was found to be at an acceptable level (r = 0.73 Cronbachs alpha).[19] Questions were systematically divided into two 12-question tests (pretest and posttest) based on results of the reliability measures, item difficulty, logical pairing of questions, and question content. The pretest and posttest were each comprised of six multiple choice and six true/false questions.

Smoking subjects (N = 129) were selected from three Primary Care clinics based in a public hospital, a veterans hospital, and a community health center. Selection criteria included being 18 years or older, English speakers, English readers, visually able to read 12 point typeset, and able to give free consent.

Subjects were randomly placed into one of three groups: control, experimental group 5 (E5), or experimental group 10 (E10). All subjects were first administered the pretest. Control group subjects (N = 44) received no smoking booklet. Subjects in E5 (N = 44) received a smoking booklet written at grade 5 reading level, those in E10 (N = 41) one written at a grade 10 reading level.

All subjects were administered the posttest, the Wide-Range Achievement Test (WRAT) Level II (a word recognition test which estimates reading grade level)[20] and were then asked questions about their educational background and other demographic information.

Results

The sample was comprised of 74 males (57 percent) and 55 females (43 percent); ages ranged from 18 to 88 with a mean of 43 years. There were 85 Blacks (66 percent) and 44 Whites (34 percent). Chi-square analyses revealed that there were no significant differences in sex, ethnic background, income, education, or WRAT between control, E5, or E10. Age was significantly different between the groups, with a mean of 49 years for control, 41 years for E5, and 40 years for E10. The mean grade level of reported education among subjects was grade 11 and the mean grade level according to the WRAT was grade 7, a difference of 4 grades (paired t = 12.62, 95% CI: 3.31, 4.52).

Prescores, postscores, and score differences were calculated for the three groups (Table 1). The score improvement (Postscore − Prescore) ÷ Prescore, showed a 4 percent increase in scores for the control group, a 22 percent increase for E5, and a 9 percent increase for E10. Using one-way analysis of variance, no significant differences were found in the prescores between control, E5, or E10. Significant

TABLE 1—Summary of Scores by Booklet Group

Range	Booklet Groups		
	Control (N = 44)	E5 (N = 44)	E10 (N = 41)
Prescore (3,12)			
Mean	6.68	7.25	7.17
SD	2.42	2.16	2.24
Postscore (1,12)			
Mean	6.93	8.82	7.80
SD	2.50	2.33	2.84
Score Difference (−6,6)			
Mean	0.25	1.57	0.63
SD	2.28	2.54	2.38
95% CI	(−0.44,0.94)	(0.80,2.34)	(−0.12,1.39)
Score Improvement (Postscore − Prescore) ÷ Prescore	3.7%	21.6%	8.7%

TABLE 2—Comparison of Scores by Booklet and WRAT

Groups	Booklet*/ WRAT	N	Prescore (Mean ± SD)	Postscore (Mean ± SD)	Score Difference	95% CI
I	Low/low	23	6.43 ± 1.75	7.87 ± 2.69	1.43	(0.21,2.66)
II	Low/high	21	8.14 ± 2.20	9.86 ± 1.24	1.71	(0.70,2.73)
III	High/low	20	5.90 ± 2.00	6.05 ± 2.86	0.15	(−1.11,1.41)
IV	High/high	21	8.38 ± 1.77	9.48 ± 1.54	1.10	(0.19,2.00)

*Low booklet = 5th grade reading level booklet
High booklet = 10th grade reading level booklet
High WRAT = WRAT score > grade 7
Low WRAT = ≤ grade 7

differences were found between the groups in their postscores ($p = 0.0033$), and in their raw score differences ($p = 0.0335$).

Subjects in groups E5 and E10 ($N = 85$) were subdivided into four groups according to their WRAT score and grade level of booklet received (Table 2). Definitions for high and low booklet and high and low reader were based on expected reading proficiency of subjects within a two year range of the readability of the available study booklets. A comparison of scores was then conducted to investigate differences between the groups.

Results indicated that subjects with high WRAT scores had higher prescores and postscores than subjects with low WRAT scores. The largest score differences (1.43 and 1.71) were noted in the groups (I and II) who received the fifth grade booklet regardless of their WRAT scores. The group which exhibited the smallest increase in score difference (0.15) was the low reader who received the tenth grade booklet (Group III).

Using the prescore and WRAT as covariates, results indicated that the booklet had significant main effects on score differences ($p = 0.0002$). Adjusted score difference means for control was 0.08 (SEM = 0.3028), for E5 was 1.73 (SEM = 0.3005), and for E10 was 0.81 (SEM 0.3115).

Discussion

Since education has been noted as a factor in smoking cessation programs, success may be related to the participants' acceptability and understandability of the information.[1] Our results support the need for continued development of educational materials at low reading levels. Producers of literature on smoking need to apply reading analyses to their texts. Readability formulas can assist in estimating the reading level of materials by offering an objective measure of text difficulty. Factors such as format, visual appeal, patient interest, and motivation also need to be considered when writing health messages.

We suggest that user tests (pretests and posttests) be incorporated into smoking cessation programs to help determine if a message is being comprehended by the participant. Such tests can offer information on clients' smoking knowledge over time when planned interventions are administered.[21–23]

Findings also indicated that educational level is a poor predictor of reading ability. Years of schooling do not identify reading ability, a finding supported by other investigators.[9,11,14,24] We suggest that an instrument such as the WRAT be used as a more accurate predictor of reading skills. The WRAT can be administered and scored in a manner of minutes.

Cigarette and Smokeless Tobacco Use among Connecticut Adolescents

S. Stephen Kegeles, PhD, Joseph A. Burleson, PhD, and Juliet Miozza, BA

Abstract: Despite data that the rate of boys' cigarette use has declined nationwide, boys' total tobacco use may actually have remained high because of their substantial use of smokeless tobacco. We surveyed anonymously a random sample of entire classes of grade 7–12 boys and girls from 59 Connecticut towns concerning tobacco use. Despite girls' higher daily cigarette use, boys' total daily tobacco use was higher than that of girls in grades 7–9, and only slightly lower in grades 10–12. (*Am J Public Health* 1989; 79:1413–1414.)

Introduction

Boys' cigarette use has generally been perceived as having peaked in the late 1960s (14.7 percent regular use in 1968 across grades 7–12), declined by 1979, and stabilized[1] with girls smoking more than boys. In a 1979 survey of grades 7–12, girls reported regular smoking at a rate of 12.7 percent and boys 10.7 percent.[1] The annual National Institute on Drug Abuse (NIDA) survey of high school seniors indicates a daily smoking rate of 18.7 percent in both 1986 and 1987 and a monthly rate of 29.4 percent in 1987, consistent since 1979.[2]

The mid-1970s might have marked the beginning of a large increase in adolescent smokeless tobacco use, first recognized in print a few years later.[3,4] By the time of the Surgeon General's 1986 report on smokeless tobacco,[5] it was apparent that many boys were using smokeless tobacco in grade school and continuing its use throughout high school. Minimal smokeless tobacco use by females has been reported except in particular regional pockets.[6–11] Since many effects of the two products are identical, it seems appropriate to document total tobacco use for both girls and boys.

As part of our research on smokeless tobacco use, we conducted a 1987 statewide survey in Connecticut assessing total tobacco use in grades 7–12. Based on surveys,[5,12] and on earlier data from Massachusetts,* we expected to find relatively low smokeless tobacco use.

Methods

Subjects and Design

All 169 Connecticut towns were blocked by population density and socioeconomic status (SES). Within the resultant matrix, proportional numbers of towns were chosen randomly, and middle and high schools were selected randomly from these towns. Requests were made sequentially to public school superintendents (75 percent agreed) and then to principals (89 percent agreed) for permission to collect anonymous, self-administered student questionnaires. Schools whose superintendents or principals refused permission were replaced with schools of similar population density and SES. Schools were asked to choose entire classrooms of students such that either regular or a combination of high and low academic track students would be represented. Further blocking by sex and grade within school was carried out in order to collect approximately 3 percent of all Connecticut students in grades 7–12 representing public, town-based schools.

Questionnaires, which were sent to and returned from schools by mail, took approximately 35 minutes to complete. Teachers were instructed to administer the questionnaires in a standardized fashion to students present at day of assessment.

Smokeless tobacco and cigarette daily use rates were determined separately by respondents' selection of one of 10 use-rate categories. Separate questions assessed "chewing leaf tobacco" and "dipping oral snuff." Previous focus group discussions had indicated that few adolescents used leaf tobacco, but nevertheless called both forms "chew." Although data were collected concerning brand names purchased and used, the general terms "smokeless tobacco" or "chew" best capture student terminology in this sample.

Due to school-required anonymity and the extensive sample size desired, no biochemical verification procedures were employed and no attempt was made to track absentees or dropouts, making these data comparable to earlier surveys. Accordingly, younger students may have underreported tobacco use more than older students and smokeless tobacco may have been underreported more than cigarettes. We received 7,457 usable questionnaires from 106 schools from 59 towns.

Results

Cigarette Use

As expected, there was a positive linear grade trend for smoking peaking at grade 11. Averaged across all grades, boys (11.2 percent) and girls (13.8 percent) reported smoking cigarettes daily at statistically different rates (see Table 1). The reversal from the boys' higher daily use rates in grades 7–9 (9.1 percent versus girls' 7.6 percent) to grades 10–12 (boys, 13.2 percent; girls, 20.7 percent) reflects a significant sex by grade interaction.

Smokeless Tobacco Use

Only 5.7 percent of girls had ever tried smokeless tobacco compared to 36.7 percent of the boys, a reliably large difference. Daily use by girls across the entire sample was only 0.3 percent, while daily use for boys across all grades averaged 5.5 percent, reaching 8.0 percent by grade 12. Weekly rates, although higher, paralleled daily rates. For boys, the higher the grade, the higher the daily smokeless tobacco use.

Total Tobacco Use

Total daily tobacco use, defined as daily use of either cigarettes or smokeless tobacco, increased significantly by grade, peaking at grade 11. Averaged across all grades, total tobacco use was comparable for girls (14.1 percent) and boys (14.8 percent). Like cigarette use, total tobacco use was

NOTE: Use of a cigarette is derived in the text by combining the rate of cigarette use with cigarette plus smokeless tobacco use. Smokeless tobacco use is calculated in analogous fashion.

higher for boys (12.0 percent) than girls (8.0 percent) for grades 7–9, while girls' use (20.9 percent) was higher than boys (18.5 percent) for grades 10–12.

Discussion

Boys' cigarette use seemed to fluctuate less by grade than did girls' use. However, between one-fourth and one-half of total daily tobacco use by boys is from smokeless tobacco. As noted in previous research,[14] the lower overall use of tobacco in grade 12 might be accounted for by a higher school dropout rate for tobacco users. Data from Connecticut, a relatively low-use state for smokeless tobacco, suggest previous underestimation of the extent of smokeless tobacco use among adolescent boys in the Northeast. This implies that the national reduction and comparatively low rate of boys' cigarette smoking over the past decade may have been compensated for by an increase in smokeless tobacco use. In fact, boys' total tobacco use may have been comparable to girls' use over these years.

Accordingly, school-based educational efforts need to focus on use of both substances. Questionnaire responses indicated that smokeless tobacco is popular because of the belief that "it is less harmful than cigarettes," "does not hurt others," and "can be done anywhere." While health education may have had an impact on knowledge and attitudes concerning cigarette smoking, smokeless tobacco use is thus not defined by male adolescents as equally dangerous. In Connecticut, legislation to restrict school tobacco use has rarely included smokeless tobacco.

Mentholated Cigarette Use among Multiphasic Examinees, 1979–86

STEPHEN SIDNEY, MD, IRENE TEKAWA, MS, AND GARY D. FRIEDMAN, MD

Abstract: Mentholated cigarette use was studied in relation to age and race in 29,037 current smokers who were Kaiser Permanente Medical Care Program members. The percentages of mentholated cigarette users were much higher in Blacks and Asians than in Whites, especially in the younger age groups. A marked inverse relationship between mentholated cigarette use and age was present in Blacks and Asians; mentholated cigarette use showed little difference with age in Whites. (*Am J Public Health* 1989; 79:1415–1416.)

Introduction

For a prospective cohort study to determine the health effects of smoking low-yield cigarettes, information was collected from 1979 to 1986 about the smoking habits of members of Kaiser Permanente Medical Care Program who participated in multiphasic health check-ups. Data from this study regarding mentholated cigarette use were analyzed for this report to determine whether previous reports of greater mentholated cigarette use in Blacks would be confirmed in our study population and to study age trends.[1,2] Data regarding Asians are included in this report because of the substantial number of Asian smokers in the study population.

Methods

An automated multiphasic health checkup has been offered since 1964 to about 25,000 persons per year at the Kaiser Permanente Medical Care Program medical centers in Oakland and San Francisco.[3] Starting in July 1979, examinees were asked to complete a supplementary questionnaire that explored their smoking habits in detail.[4] In mid-1980 the check-up was discontinued at the San Francisco facility. By the end of 1986, the questionnaire had been completed by 114,934 examinees (approximately 86 percent of the examinees), of whom 31,428 (27.3 percent) were current smokers. Information on whether or not the cigarettes were mentholated was available for 92 percent of the current smokers. The tar yield was obtained from Federal Trade Commission estimates for each brand and type of cigarette.

If subjects had more than one check-up, only the first was included in this analysis. Age-adjusted proportions of mentholated cigarette users were obtained by the direct method, with the age distribution of the entire study population used as the standard. Mentholated cigarette use habits were examined in the 29,037 current smokers ages 15–79 years of Black, White, or Asian race.

Results

The sex, race, and age distribution of the current smokers is shown in Table 1. The percentage of mentholated cigarette use was higher in women than in men in all age groups for Blacks and Whites, and in most age groups for Asians (Figure 1). There was a marked inverse relationship between age and mentholated cigarette use in Blacks and in Asians, while there was relatively little difference in mentholated cigarette use with age in Whites. Blacks had the highest age-adjusted proportion of mentholated cigarette users (55.5 percent for females, 49.9 percent for males), Asians the second highest (47.9 percent, females, 35.7 percent, males), and Whites the lowest (27.1 percent, females, 18.1 percent, males).

The mean number of cigarettes smoked per day (adjusted for age, race, and sex) was slightly lower in mentholated than in nonmentholated users: 16.2 versus 17.1; 95% confidence interval of the difference = −1.2, −0.7. Mentholated cigarette users were similar to nonmentholated users in their reports of how often they inhaled, depth of inhalation, and how much of the cigarette they smoked. Alhough the mean tar yield of mentholated cigarettes was lower than that of nonmentholated cigarettes for both Blacks (15.5 mg vs 16.0 mg) and Whites (13.8 mg vs 14.0 mg), the mean tar yield of cigarettes smoked by Blacks (adjusted for age and sex) was greater than that of Whites (15.9 mg vs 14.1 mg, 95% CI of the difference 1.7, 2.0).

The switching patterns between mentholated and nonmentholated brands were examined in the 1,688 Black smokers under the age of 40 years for whom follow-up information regarding smoking habits was obtained by a mailed questionnaire (mean interval between baseline questionnaire and follow-up was 4.5 years). Follow-up information was obtained on a slightly greater proportion of nonmentholated than mentholated cigarette users (32 vs 28 percent). The percentage of quitters was slightly higher in nonmentholated users than in mentholated users (17.5 vs 15.4 percent), while the percentage of switchers (from nonmentholated to mentholated or vice-versa) was much higher in the nonmentholated users (14.6 vs 3.6 percent). Using a proportional hazards model to adjust for age and sex and to account for varying length of follow-up, nonmentholated users were 4.2 times more likely to switch than mentholated users (95% CI 2.8, 6.4), while quitting was equally likely in both groups.

Discussion

As others have reported, we found a much higher proportion of mentholated cigarette use in Black smokers than in White smokers. There is a very strong inverse relationship between age and mentholated cigarette use in Blacks. The data suggest that

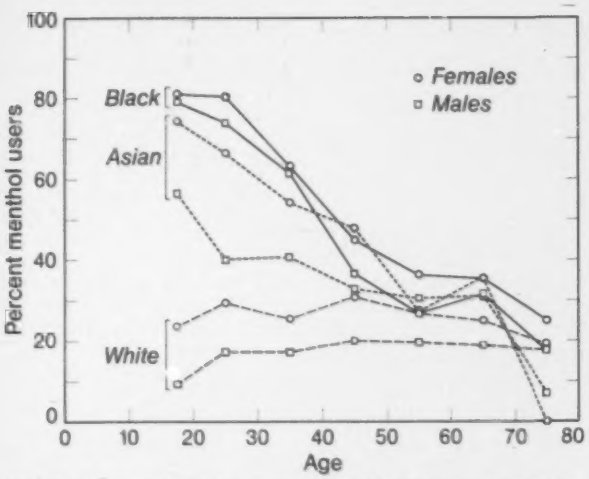

FIGURE 1—Percent Menthol Users among Current Cigarette Smokers by Race, Sex, and Age

the steep decline in the proportion of mentholated cigarette users with age in Blacks can be explained predominantly as a cohort effect, since the findings regarding switching from cigarettes of one mentholation status to another in this study suggest that the prevalence of mentholated cigarette use increases over time in younger Black smokers.

There are few data on the health effects of mentholated cigarettes. A recent case-control of esophageal cancer showed no significant change in risk due to mentholated cigarette use.[5] Our findings have potentially important implications for research into the health effects of mentholated cigarettes. The rates of some smoking-related cancers (e.g., esophagus, lung) are more common in Blacks, at least in part because Blacks are more likely to be smokers.[4] A theoretical basis for a causal relationship between mentholation and cancer exists in that menthol combustion produces carcinogenic compounds such as benzo[a]pyrenes.[5] It has also been hypothesized that the cooling sensation due to menthol may allow deeper, prolonged inhalation of cigarette smoke, thereby increasing the effective yield of tar and other toxic chemicals from the cigarette.[5] This study did not show self-reported differences in inhalation habits between Blacks and Whites, but that may well be due to the anesthetizing effects of menthol.

If mentholation does cause cancer, it may contribute substantially to the excess incidence of certain smoking-related cancers in Blacks relative to Whites. A potential consequence of the very large differences in the prevalence of mentholated cigarette use in younger Blacks relative to Whites would be a widening of the difference between Blacks and Whites of these incidence rates in the future, when younger Blacks reach the higher risk age range for cancer.

State-Specific Progress Toward the 1990 Objective for the Nation for Cigarette Smoking Prevalence

PATRICK L. REMINGTON, MD, MPH, THOMAS E. NOVOTNY, MD, DAVID F. WILLIAMSON, MS, PHD, AND ROBERT F. ANDA, MD, MS

Abstract: We predicted the smoking prevalences for 1990 for each state in the US, assuming that the decline in each state from 1985–1990 would be the same as the decline in the US from 1965–1985. In 1985, only three states had smoking prevalences less than 25 percent. Based upon the observed decline in smoking in the US from 1965–1985 of 0.5 percent per year, we predict that only seven states will have smoking prevalences less than 25 percent by 1990. States need to consider current smoking prevalence and achievable rates of decline when setting objectives for 1990 and beyond. (*Am J Public Health* 1989; 79:1416–1419.)

Introduction

As part of its 1990 Health Objectives for the Nation, the US Public Health Service has established a goal that by 1990 the proportion of adults who smoke should be reduced to less than 25 percent.[1] A recently published midcourse review indicated that this objective likely will be met.[2] Despite the apparent success at the national level, however, the variation in the prevalence of smoking from state to state[3] suggests that a prevalence of smoking of less than 25 percent may not be an achievable objective for all states. To address this issue, we predicted 1990 smoking prevalences for all 50 states and the District of Columbia by applying a range of estimates of decline in smoking prevalence to the observed state-specific smoking prevalences for 1985.

Methods

The state-specific smoking prevalence estimates were based on data obtained in September 1985 from the Current

Population Survey conducted by the Bureau of the Census.[4] In the Current Population Survey, 60,000 households were surveyed in 1,973 counties, cities, and minor civil divisions in the United States. The data were weighted by age, sex, and race to represent the total civilian, non-institutionalized population of each state. To have estimates comparable with previously published national data, we included only persons 20 years of age or older. Current smokers were defined as persons who had smoked 100 or more cigarettes in their lifetimes and who currently smoked. When respondents were not available at the time of the household interview (59 percent of men, 27 percent of women, 42 percent overall), their smoking status was provided by proxy.

We used data from the National Health Interview Surveys from 1965, 1976, 1980, and 1985 to estimate various rates of decline in smoking prevalence among all adults 20 years of age and older. These estimates were age-adjusted to the 1985 US adult population.[5] A current smoker was defined as a person who had smoked at least 100 cigarettes and who smoked at the time of the survey. Proxy responses were not used in the National Health Interview Surveys.

The annual rate of decline in smoking prevalence from 1965–1985 was applied to each state's smoking prevalence in 1985, to project a smoking prevalence for 1990. To account for possible variability in the rate of decline from state to state, we performed a sensitivity analysis. We similarly projected state-specific smoking prevalences for 1990 using 2 times and ½ times the observed rate of decline from 1965–1985. This range in the rate of decline was subsequently compared to the rates of decline in each inter-survey period (1965–76, 1965–80, 1976–80, 1976–85, and 1980–85) in the US. We used the actual state prevalence estimates in all calculations, rounded to the nearest percent for presentation.

Results

In the United States between 1965 and 1985, the age-adjusted prevalence of smoking among adults 20 years of age or older decreased from 40.4 to 30.4 percent, a rate of decline of 0.50 percent per year. In 1985, state-specific smoking prevalences ranged from 15 percent in Utah to 37 percent in Nevada; only three states had smoking prevalences less than 25 percent (Figure 1). If the observed annual rate of decline in the United States from 1965–1985 occurs in each state from 1985–1990, only four additional states will have smoking prevalences less than 25 percent by 1990.

The results of the sensitivity analysis are presented in Table 1. If the decline from 1985–1990 is one-half the observed decline from 1965–1985 (0.25 percent per year), then only three states will have prevalences less than than 25 percent by 1990. Conversely, if the annual decline from 1985–1990 is two times the observed national decline from 1965–1985 (1.0 percent per year), then 25 states will have prevalences less than 25 percent.

The lower bound of the estimate for decline in smoking used in the sensitivity analysis (0.25 percent per year) is less than any decline observed between 1965–1985 (0.39 percent per year between 1965–1976). Similarly, the upper bound of the estimate (1 percent per year) is greater than any decline observed during that period (0.7 percent per year from 1976–1980). When these are applied to the 1985 US smoking prevalence, we predict a smoking rate for the US in 1990 of 27.9 percent (range 25.4 percent to 29.1 percent) (Figure 2).

Discussion

Using national data on the decline in smoking prevalence, we predicted the prevalence of smoking for each state for 1990. We have shown that few states will have smoking prevalences less than 25 percent by 1990, assuming that the decline observed in the United States from 1965–1985 occurs

*Trend data from the National Health Interview Surveys were used to estimate the range in rates of decline in smoking for each state from 1985 to 1990. The 1990 projected prevalences were made using the actual 1985 state-specific prevalence but are rounded to the nearest percent for presentation.

**The prevalences for 1985 are from the 1985 Current Population Surveys, for adults 20 years of age or older.

†Smoking prevalence less than 25 percent.

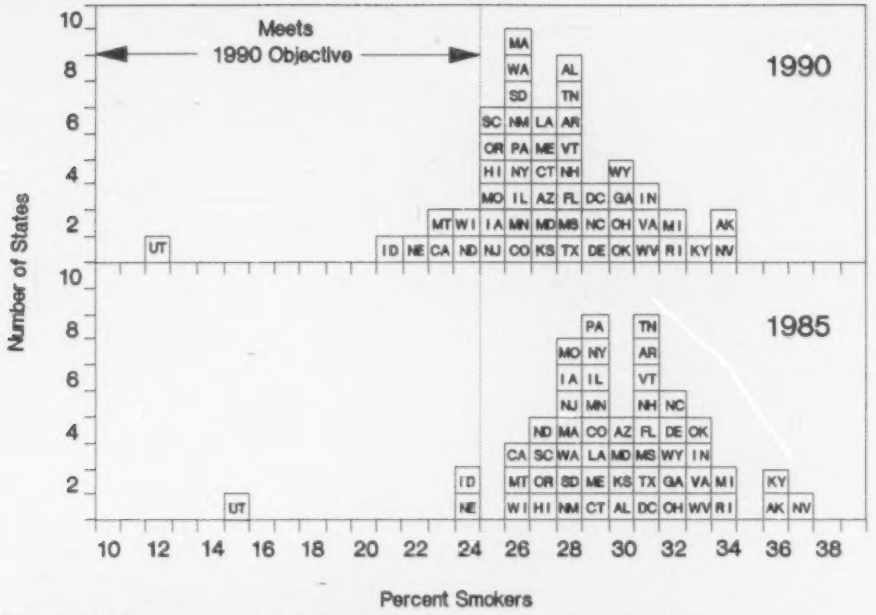

FIGURE 1—Distribution of State-Specific Smoking Prevalences in 1985 and Projected for 1990
Data for 1985 are from the Current Population Surveys for adults 20 years of age or greater. Rates for 1990 are projected assuming a 0.5% annual decline in smoking in each state from 1985–1990. Each square is identified with its 2-digit state abbreviation.

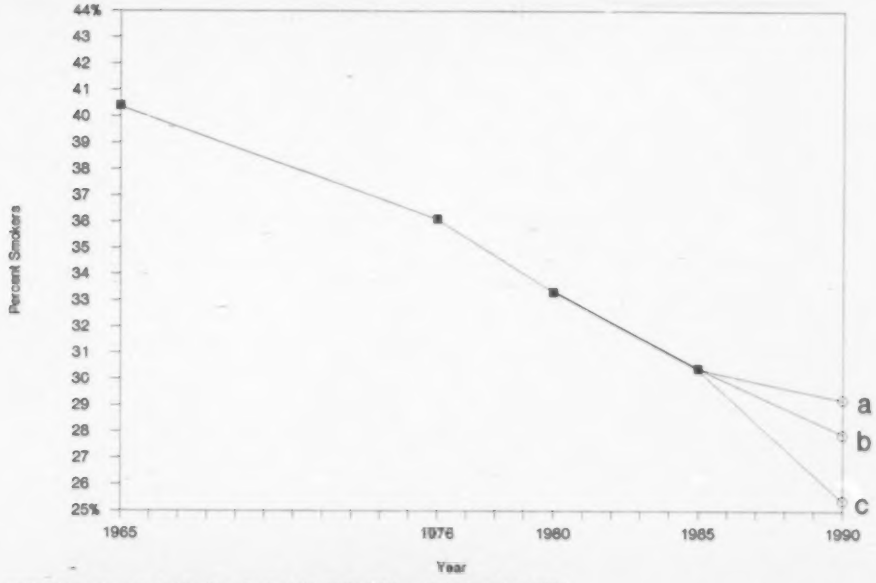

FIGURE 2—Trends in Smoking in the US, 1965–1985 and Projected to 1990
Data for 1965, 1976, 1980, and 1985 are from the National Health Interview Surveys for adults 20 years of age or greater, and are age-adjusted to the 1985 U.S. population. Rates for 1990 are projected assuming an annual rate of decline of 0.25%/year (a), 0.5%/year (b), and 1.0%/year (c), respectively.

in each state from 1985–1990. In fact, in contrast to the conclusion of the Midcourse Review, our analysis suggests that it is unlikely the prevalence of smoking will be less than 25 percent in the United States overall by 1990.

When setting objectives for cigarette smoking prevalence for 1990 and beyond, it is important to consider the methods that will be used to monitor progress toward achieving that objective. For example, although the surveys used in this report were both in-person surveys, slightly different methods were used to assess the prevalence of smoking. In the

TABLE 2—Trends in the Prevalence of Smoking for Adults 20 years of age or greater, United States, 1965–1985

Year	Percent Smokers	Percent Decline/Year from 1965	from 1976	from 1980
1965	40.4	—	—	—
1976	36.1	.39	—	—
1980	33.3	.47	.70	—
1985	30.4	.50	.63	.58

Data are from the National Health Interview Surveys for adults 20 years of age or greater, and are age-adjusted to the 1985 US Census[5]

National Health Interview Survey, respondents were directly questioned about their smoking habits, whereas in the Current Population Surveys, proxy responses were commonly used to determine their smoking status (59 percent of the responses among men were provided by proxy).

When possible, it is important to use state-specific information on trends in smoking when setting objectives. Many states now use data from the Behavioral Risk Factor Surveillance System to estimate the prevalence of smoking.[6] However, telephone surveys generally provide smoking estimates lower than those obtained from in-person surveys. The prevalence estimates from the 22 states that conducted random digit-dialed (self-respondent only) telephone surveys as part of the Behavioral Risk Factor Surveillance System in 1985 were, on the average, 2 percent to 3 percent less than the in-person estimates provided in this report.[3] These lower estimates likely result from telephone noncoverage and lower response rates among smokers in telephone surveys.[7] Nevertheless, this surveillance system has proven useful to states and should be used in the future to set objectives and monitor trends in smoking if these biases are accounted for.

Although predicting smoking prevalences in any state five years hence is difficult, this paper provides a range of estimates that states may consider when setting their own objectives. Because many programs to reduce the prevalence of cigarette smoking are implemented at the state level, it is important for each state to set reasonable objectives for the future.[8] One of the purposes in setting forth an objective is to promote new initiatives. Therefore, selecting a target that will be reached without intervention is inappropriate. Similarly, setting objectives that are clearly not achievable is equally inappropriate. To this end, we hope that this report encourages setting objectives based on a careful review of available data and an assessment of the likely impact of future intervention efforts.

The News on Smoking: Newspaper Coverage of Smoking and Health in Australia, 1987–88

SIMON CHAPMAN, PHD

Abstract: All newspaper articles (n = 1601) mentioning tobacco or smoking drawn from a 12-month census of 30 Australian capital city newspapers in 1987–88 were coded for content, "slant," and apparent origin. Overall, 62 percent of articles were positive in their orientation toward smoking control objectives, 17 percent were negative, and 21 percent were neutral. Newspapers owned by Rupert Murdoch published 55.7 percent positive and 23.7 percent negative articles compared to 68.0 percent positive and 13.7 percent negative articles in the other large chain of Australian newspapers. (*Am J Public Health* 1989; 79:1419–1421.)

Address reprint requests to Simon Chapman, PhD, Lecturer in Community Medicine, University of Sydney, Westmead Hospital, Westmead, New South Wales 2145, Australia. This paper, submitted to the Journal January 23, 1989, was revised and accepted for publication May 17, 1989.

Introduction

Male smoking prevalence has declined in Australia from an estimated 72 percent in 1945[1] to a 1986 level of 31.9 percent.[2] Female smoking prevalence has risen slightly in the same period from 26 percent[1] to 28.8 percent.[2] Almost all of the commentary on this decline in male smoking rates has been preoccupied with the impact of government-sponsored and health agency-sponsored mass health information and persuasion campaigns,[3] and the introduction of smoking control legislation and regulation.[4–7]

Since 1983, most States in Australia have conducted mass-media-based public awareness campaigns although the largest of these efforts has had a budget considerably less

© 1989 American Journal of Public Health 0090-0036/89$1.50

than the typical cigarette advertising campaign.

Preoccupation with the impact of defined public sector interventions—such as purchased media time and space, school programs, and smoking cessation efforts—has tended to obscure the impact of a principal means by which the public is exposed to messages about smoking: the news media. This study reports a content analysis of a census of all coverage of smoking issues in capital city newspapers in Australia in a sample period in 1987–88.

Methods

All articles dealing exclusively with or mentioning tobacco or smoking published in all 30 Australian capital city newspapers were obtained from a commercial press clipping service for the 12 months May 1987–April 1988. The newspapers included "quality" and popularist newspapers and Sunday editions. A total of 1,601 clippings were thus obtained.

Coding

Each clipping was coded for the publication in which it appeared; date of publication; type of item (news item, feature article, news brief, letter, editorial); apparent origin; principal content; and its "slant" or orientation. These classifications are described in the Appendix. To assess whether the coder's ratings for slant were idiosyncratic, a randomly selected subsample of 1 percent of the clippings (16 articles), was coded by nine peope working in four different smoking control agencies around Australia; a Cohen's Kappa of 0.84 was obtained, indicating high inter-coder reliability (external validity).[8]

Table 1 shows the principal content of all articles, cross-tabulated by slant. News and commentary on the December 1987 ban on smoking on all domestic airlines (187 items), and on the introduction of the Victorian Tobacco Control Act (106 items) which banned all outdoor and cinema tobacco advertising in that State and raised State tax on tobacco, were widely covered. Articles on passive smoking appeared at 125 percent greater frequency than the next most common principal category (advertising and promotion).

When articles were classified by type of article and slant (Table 2), there was a similar distribution for all main categories with the predictable exception of the fewer neutral letters.

Newspaper ownership in Australia is dominated by two main groups, News Corporation owned by Mr Rupert Murdoch, and John Fairfax and Sons. Positive articles in Murdoch-owned papers (55.7 percent) were less common, compared to Fairfax-owned (68 percent) and other-owned (62.2 percent); negative articles were more common in Murdoch papers (23.7 percent), compared to 13.7 percent in Fairfax-owned and 17.2 percent in other-owned.*

When articles were classified by apparent origin and slant (Table 3), the expected polarizations toward positive articles generated or written by health workers, agencies, and physicians, and negative articles inspired or written by the tobacco and advertising industries were found.

Discussion

Because this study examined only one year of publications in one country, no longitudinal or international comparisons can be made. Comparisons of prevalence with articles on drugs or alcohol would require explicit but debatable hypotheses about some ideal level of equivalence or difference and tone of reporting about various topics. In the absence of any reasonable or accepted standards of what ought to be the frequency of tobacco reporting, little can be concluded, other than to suggest that any notion that Australian newspapers are loathe to print items that may offend their tobacco advertisers carries little support.

Evidence from the USA,[9–12] and Australia[13] has demonstrated that there is an inverse relation between the acceptance of tobacco advertising by magazines and the appearance of articles on tobacco. Because all of the newspapers in this study accepted tobacco advertisements, this is not the case with this sample of newspapers in Australia. While Australian newspapers in the past have leaned more toward a negative coverage of proposed bans on tobacco advertising,[14] the evidence here shows no support for the "gag of the tobacco dollar" view. Despite the Murdoch-owned newspapers printing more negative articles than those

TABLE 1—Principal Content of Tobacco-Related Articles by Slant

Slant of Article	Total	Positive (%)	Negative (%)	Neutral (%)
Passive smoking	534	319 (59.4)	117 (21.4)	98 (18.2)

owned by other publishers, Murdoch newspapers still published 2.4 times as many positive articles as negative.

Explanations of the difference between the apparent editorial or owners' policies with US magazines and Australian newspapers require further study, but may lie in two directions: First, articles in magazines are often planned well in advance and therefore may be open to considerably more explicit or latent censorship than those submitted by journalists in the more immediate world of newspaper writing. However, this view would appear to hold little credence in this study: 114 feature-length articles on tobacco were coded, of which 61 percent were positive and only 11 percent negative, the lowest negative proportion for any major category of article. Like magazine journalism, feature article writing in newspapers is often directed from editorial level down to journalists, so the evidence suggests a newspaper editorial climate conducive to the production of "good news" on smoking in Australia.

The second explanation is that tobacco advertising is more economically important to magazines than to newspapers and that magazines would be thus less inclined to "bite the hand that feeds them." *The Age* newspaper, which ran many more articles on tobacco than any other in the sample, receives about $1.00 from cigarette advertising for every $200 from all advertising,[15] compared to about $1 in $60 for newspapers generally.[16] Australian magazines, by contrast, receive about twice the total proportion of advertising dollars from tobacco as do newspapers.[16] This explanation is more consistent with the greater and more positive coverage of smoking issues in newspapers compared to that in magazines.

APPENDIX A

Coding Classification

Principal content was first coded liberally, and then subsumed into six principal classifications (passive smoking, advertising and promotion, smoking cessation, health issues, taxation, and miscellaneous). "Origin" refers to the apparent origin of the item. News items appear after a process of selection by journalists and editors about what is newsworthy. This selection occurs from sources which frequently include groups with explicit interests in having certain views of issues appear in print. Both the promotion and control of smoking are issues which have vested interest groups keen on having the media publicize news and commentary favorable to their respective interests.[17] A 1973 study of nearly 3,000 items published in the *New York Times* and the *Washington Post* found that 58.2 percent of stories came from "routine" channels (press releases, semi-official documents etc).[18] The concept of "pronunciamento"[17]—or the direct transfer of information, ideas or accusations from interest groups to readers via virtually unaltered transcripts of their press releases—appeared to be applicable to many items in the sample.

"Slant," coded either positive, negative, or neutral/not applicable, refers to the extent to which any article could reasonably be said to be supportive of a social climate antithetical to smoking. Such judgment begs the question of who is doing the judging.[19] I approached this by considering how a person concerned to advance smoking control objectives would judge any given article. Would a smoking control advocate be pleased or displeased to see a particular article appearing in print? Articles judged as being likely to be read by a person favorably disposed toward smoking control, as enhancing the general view that smoking and those institutions, interests, laws and policies that support it are undesirable were coded "positive." Articles that would be understood by such a person as conveying a view of smoking as in some way positive, relatively unimportant compared to other issues, or which were critical of laws, policies and individuals advocating restricting or opposing smoking were coded "negative". Articles which were judged as being neither clearly positive or negative, which evidenced a clear attempt at balancing health and tobacco industry views, or which were simple announcements about (for example) a forthcoming rise in tobacco excise, were coded "neutral/not applicable."

Influenza Immunization in the Elderly: Knowledge and Attitudes Do Not Explain Physician Behavior

W. Paul McKinney, MD, and Gary P. Barnas, MD

Abstract: The records of 847 elderly clinic patients were reviewed and the 95 primary care physicians who managed their care were surveyed to determine factors related to their ordering of influenza immunization. Overall, 41 percent of the eligible patients were offered vaccine (range 0–90 percent). Physician offering of vaccine was unrelated to patient age, sex, or race but was higher in patients seen on multiple visits (47 vs 39 percent) and in those vaccinated during the prior year (61 vs 35 percent). Physician offering of vaccine was not associated with perceived incidence of severe side effects or estimates of vaccine efficacy. (*Am J Public Health* 1989; 79:1422–1424.)

Introduction

The elderly have been shown to be at high risk of death and serious illness following influenza infection.[1,2] The Centers for Disease Control[3] and the American College of Physicians[4] have recommended that routine annual influenza immunization be offered to all patients age 65 and older. Such immunization has been shown to be a cost-effective preventive health practice.[5–7] However, less than 20 percent of those over age 65 or otherwise considered to be at high risk receive influenza vaccination each year.[8]

Previous studies have evaluated factors influencing patients' decisions to receive or refuse influenza vaccine,[9–12] but there is little information about what affects physicians decisions to offer vaccination. Physicians appear to know the indications for use of the vaccination, but fail to translate this knowledge into clinical practice.[13]

We studied the frequency and determinants of influenza immunization to see whether differences in physician attitudes, knowledge, or perceived side effects of the vaccine could account for the variation in immunization practices.

Methods

All patients age 65 and older seen in the Primary Care Clinic at the Milwaukee County Medical Complex from October through December of 1984 were identified and their medical records reviewed to determine if they were offered influenza vaccination. Patients were considered eligible if they had not already been vaccinated that season, had no history of egg anaphylaxis or severe reaction to prior vaccination, and did not have an acute febrile illness. Immunization was considered to have been offered by the physician if an order was written or if the patient's refusal of immunization was noted. Demographic data, history of influenza vaccination the prior year, and the type of patient visit (continuing care or visit to a different physician) were also recorded.

Following the study period, a telephone survey was conducted by a non-medical interviewer of all 95 physicians (90 residents and five faculty) who provided direct patient care. Rates of offering influenza vaccine were calculated for the 82 physicians (77 residents and five faculty) who saw at least five eligible patients during the study period. Categorical data were analyzed using the chi square statistic and correlation coefficients (Pearson) were calculated for continuous variables.

Results

The charts of 847 (99.2 percent) of the 854 patients age 65 years and older seen during the study period were reviewed; 812 were eligible for influenza immunization. Overall, 332 (41 percent) of those eligible were offered vaccine; however, individual physicians varied widely in their rates of offering vaccine to their patients, with a range of 0–90 percent. Vaccination was refused by 9 percent of those to whom it was offered. Patient demographics, clinic visit characteristics, and their relation to being offered vaccine are shown in Table 1. Vaccination during the prior calendar year was the strongest determinant of being offered vaccine.

The telephone-administered questionnaire was completed by 88/90 residents and four of five faculty (97 percent overall). Over 80 percent knew the recommended time of year to vaccinate, that influenza vaccine can be given simultaneously with pneumococcal vaccine, and that the objective of influenza immunization is to reduce morbidity and mortality. More than 75 percent correctly responded that influenza immunization is contraindicated in the presence of an acute febrile illness or history of egg anaphylaxis. However, 40 percent incorrectly thought that use of systemic steroids contraindicated vaccination.

Many physicians overestimated the occurrence of rare or unrecognized side effects. Anaphylaxis was estimated to occur >1 percent of the time by 25 percent of physicians, and Guillain-Barré syndrome was believed to occur in >1 percent of recipients by 15 percent of physicians. No association was found between vaccine offering rates and knowledge of incidence rates for anaphylaxis or Guillain-Barré syndrome.* Most physicians (69 percent) considered influenza vaccine to be 70–90 percent effective in preventing infection, but estimates of high vaccine efficacy were not correlated with increased offering rates.

Table 2 shows physician attitudes towards immunizing individuals with various high-risk conditions. The category "age 65 or over" received fewer highest strength recommendations than categories of chronic obstructive pulmonary disease, asthma, residency in a nursing home, renal insufficiency and diabetes. The strength of conviction to immunize

elderly patients was only weakly correlated with offering rates ($r = .297$, $p = .004$).

Discussion

Physicians may not use influenza vaccine because of uncertainty about its indications, doubts about its efficacy, or failure to consider vaccination during patient encounters.[14] The recent report by Setia, *et al*,[13] based on 14 physicians, found that only 33 percent of 540 nursing home patients were immunized despite their physicians' strong beliefs in the efficacy and low risk of vaccination. Our study confirms that physicians' perceptions of vaccine efficacy and their strength of conviction to offer vaccination were high but still were not strongly associated with higher rates of vaccination.

While not correlated with the use of vaccine, the perceived incidence of severe vaccine side effects was markedly higher than the actual incidence reported in the literature. Anaphylaxis is an extremely rare occurrence after influenza vaccination,[15] and Guillain-Barré syndrome has not been associated with vaccination since the swine flu vaccine of 1976.[16–18] Educational efforts should emphasize the low risk of major vaccine side effects.

The overwhelming majority of physicians understood key recommendations concerning vaccine use and accurately assessed its efficacy. Other investigators[19,20] have noted that knowledge of the efficacy and recommended use of influenza vaccine does not guarantee its appropriate administration. Moreover, Cohen[20] found that educational seminars for physicians were less important than patient chart-based checklist reminders in changing vaccination behavior.

We recognize several limitations of our findings. This study was conducted in an academic hospital-based outpatient clinic and the results may not be generalizable to the community setting. Certain patients could have declined receipt of the vaccine following discussions with their physicians or have informed the physician that they received the vaccine elsewhere without documentation in the chart. However, given the relatively high offering rate and the fact that such failures would underrepresent the intent to immunize, it is unlikely that this occurred frequently. As this clinic is the sole source of care for most of this indigent population, it is unlikely that many received the vaccine from alternate sites in the community.

Attempts to increase vaccine use should focus on measures other than changing physician attitudes or increasing their knowledge about the vaccine. Strategies which do not rely on individual physician decision-making should be developed to increase appropriate vaccination of the elderly.

RWJ Foundation Grants Target Children with Mental Illness

Eleven states and the District of Columbia were selected this summer to launch a national initiative to improve services for US children with serious mental illness. The grants were awarded by the Robert Wood Johnson Foundation under its $20.4 million Mental Health Services Program for Youth.

Selected to receive one-year planning grants of $100,000 under the initial phase of the program are: California, the District of Columbia, Kentucky, Michigan, North Carolina, North Dakota, Ohio, Oregon, Pennsylvania, Vermont, Washington, and Wisconsin. Based on the strength of their plans to better coordinate and finance home- and community-based services for mentally ill children, up to eight of the projects will be awarded four-year grants of up to $2.4 million to carry out their plans. The initiative is intended to improve care for the estimated three million US children whose mental disorders—ranging from autism to depression—typically result in long-term disability or institutionalization, foundation officials said.

Directed for the foundation by Mary Jane England, MD, vice president of medical services at the Prudential Insurance Company in Roseland, NJ, the five-year program will allow states to focus their efforts on communities or geographic areas ranging in population from 300,000 to 600,000. The grants require collaboration among the many state and local agencies responsible for planning, providing and financing mental health care for children.

Since the Foundation was established as a national philanthropy in 1972, it has awarded more than $996 million in grants to improve the health of adolescents, children, the elderly, the homeless, the mentally ill, people with AIDS and others. For further information, contact the: Robert Wood Johnson Foundation, College Road, PO Box 2316, Princeton, NJ 08543-2316. Tel: (609) 452-8701.

Occupational Exposure to Human Immunodeficiency Virus (HIV) and Hepatitis B Virus (HBV) among Embalmers: A Pilot Seroprevalence Study

SALLY BUNCE TURNER, MS, LAUREEN M. KUNCHES, MPH, KATHLEEN F. GORDON, MS, PATRICIA HYLAND TRAVERS, MS, AND NANCY E. MUELLER, ScD

Abstract: We performed a serosurvey of 133 embalmers in an urban area where human immunodeficiency virus (HIV) infection is prevalent. Although we found histories of needlesticks to be common, and the seropositivity rate of hepatitis B virus (HBV) (13%) was approximately twice that of a blood donor comparison group, HIV antibody was uniformly absent in 129 embalmers who denied HIV risk factors, and present in one of four with self-described risk behaviors. The risk of HBV infection was higher among embalmers who have worked more than 10 years, relative risk (RR) 16.2 (95% confidence interval 2.1, 126.5), did not routinely wear gloves, RR 9.8 (CI 3.4, 28.5), or are employed in the city of Boston, RR 4.7 (CI 1.8, 12.0). (*Am J Public Health* 1989; 79:1425–1426.)

Introduction

There is widespread concern in the health care community about occupational exposure to human immunodeficiency virus (HIV). The occupational groups at risk of exposure are those who are also at risk of hepatitis B virus (HBV) infection. Although a substantial number of health care workers have been examined for the risk of both infections, limited information is available on the risk of HBV infection[1,2] and none is available on the risk of HIV infection to embalmers.

Previous studies have shown that HBV has greater potential for nosocomial spread than HIV.[3–7] The purpose of this pilot study is to evaluate the risk of transmission of both infections in relation to work practices in a group of embalmers working in eastern Massachusetts.

Methods

The target population was composed of embalmers from the greater Boston and Worcester, Massachusetts, metropolitan areas. Embalmers were eligible for enrollment if, in their career, they had embalmed 20 or more bodies. The data were collected over a seven-month period, from August 1986 to February 1987.

An oral questionnaire elicited demographic information regarding age, sex, ethnicity, marital status, past medical history, occupational history, and the risk factors for HBV and HIV infection: history of renal dialysis, hepatitis, cancer, bleeding disorder, blood transfusion, receipt of globulin preparation or hepatitis B vaccine, tattoos, and intravenous drug use.

All serum samples were tested for hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (HBsAb), and hepatitis B core antibody (HBcAb) by enzyme-linked immunosorbent assay (ELISA) (Abbott Laboratories, North Chicago, Illinois). Antibody to HIV was measured with the Abbott HTLV-III/LAV ELISA (Abbott Laboratories, North Chicago, Illinois). A repeatedly reactive sample was confirmed by the Western blot technique. Sera that tested positive for HBcAb were screened for antibody to the delta antigen (Abbott Anti-Delta).

Comparison of the seroprevalence among subgroups of the population are expressed as relative risks (RR), estimated by the prevalence odds ratios, with their 95 percent confidence intervals.[8] Variables shown to be risk factors for HBV were included in a logistic regression procedure (Statistical Analysis System Inc., Cary, NC) to evaluate potential confounding.

Results

Of 108 study subjects who had no history of hepatitis B vaccination, 14 (13 percent) had serologic evidence of HBV infection. Of these, HBsAg (with HBcAb) was detected in one, HBcAb alone in one, and HBsAb in 12. Of the 12 with HBsAb in serum, 11 had HBcAb as well. Therefore, the frequency of HBcAb in all participants, including those with any marker, was 9.7 percent (13 of 133). None of the study subjects with serologic markers for HBV infection had evidence of coinfection with the delta virus.

Twenty-five embalmers reported being vaccinated with hepatitis B vaccine. None of the vaccinees had evidence of infection with HBV (HBsAg or HBcAb) and will therefore be considered "seronegative" for purposes of the following analysis.

Years of employment, age, and number of bodies embalmed were significantly associated with HBV infection (Table 1). When these interrelated variables were entered into a logistic regression procedure, employment for more than 10 years correlated most strongly with prior infection (adjusted odds ratio = 85.9); no additional predictive value was added to the regression model by age or number of bodies embalmed.

Embalmers who do not routinely wear gloves were almost 10 times more likely to have serologic markers of HBV infection than those who do. Controlling for duration of employment strengthened this association (adjusted odds ratio = 16.7). No correlation was found between HBV markers and reported use of gowns or aprons, shoe coverings, goggles, glasses, or face masks.

Subjects employed in Boston were more likely to have evidence of HBV infection than those employed outside of Boston. After adjusting for years of employment and use of gloves, Boston's embalmers were 12 times more likely to have HBV markers than others. All subjects with evidence of previous infection with HBV reported sustaining one or more accidental needlesticks during their career. However, the

TABLE 1—Risk Factors for HBV Infection

Variables	Total	Serologic Evidence of HBV Infection	Relative Risk (95% CI)
Employed > 10 years as embalmer	66	13 (20)	16.2 (2.1, 126.5)
Embalmed ≥ 1000 bodies	67	12 (18)	6.9 (1.5, 32.8)
Do not always wear gloves	18	7 (39)	9.8 (3.4, 28.5)
Employment in Boston	37	9 (24)	4.7 (1.8, 12.0)
Greater than 35 years of age	67	11 (16)	3.6 (1.2, 11.2)
Eat or drink while embalming	48	7 (15)	1.8 (0.66, 4.7)
Smoke while embalming	43	6 (14)	1.6 (0.50, 4.3)

*Figures in parentheses denote percentages.

number of known HBV cases embalmed or recognized HBV needlesticks was not related to HBV infection. Three of the four subjects who disclosed non-occupational risk factors had evidence of previous HBV infection.

When information on history of previous employment in other occupations involving blood exposure was analyzed, there was no observed association with prevalence of HBV markers. Twenty-one percent of embalmers with HBV markers reported having clinically overt hepatitis in the past.

All 133 subjects were tested for antibodies to HIV. One of four self-described members of recognized high-risk groups tested positive for HIVAb; all other subjects were seronegative.

Discussion

During the embalming procedure, embalmers often come into contact with large amounts of blood as the vascular system is drained. Depending on the cause of death and whether an autopsy has been performed, they may be required to handle various body parts and tissues, to make numerous incisions and subsequently suture the incised tissue. However, compared to other health care professions, embalmers have been largely ignored by researchers evaluating the risk of occupationally transmitted infections. The results of this study indicate that embalmers are at increased risk of infection with HBV when compared to the general population,[9] but have not shown increased risk of HIV infection. Overall, the seroprevalence of hepatitis B among health care workers ranges from 5 to 32 percent.[9–15] The 13 percent prevalence of hepatitis B markers among the non-vaccinated subjects indicates that embalmers are a moderately high-risk group of health care professionals. The finding that 79 percent of these individuals had simultaneous HBcAb and HBsAb is consistent with the results of Dienstag and Ryan,[9] who reported that frequent blood exposure, and in general more intense exposure, was correlated with the prevalence of both antibodies.

Recently concern over exposure to asymptomatic HIV carriers has motivated improved infection control practices among health care workers. Embalmers currently maintain these standards for known AIDS (acquired immunodeficiency syndrome) cases, but need additional education to emphasize adherence to universal precautions. The Centers for Disease Control recommends the routine use of gloves, masks, protective eyewear, gowns, and waterproof aprons for all persons performing or assisting in postmortem procedures.[16]

The study participants recalled having embalmed a total of 298 AIDS cases, compared to 285 confirmed AIDS deaths in Massachusetts when the study was initiated. This comparison suggests that the estimates of occupational exposure to AIDS cases are accurate.

Little emphasis has been placed by this occupational group on the risk of exposure to HBV in the workplace. Because this study demonstrates that the risk of occupationally acquired HIV infection is extremely low, and the risk of occupationally acquired HBV infection is substantial, emphasis should be placed on prevention of transmission of HBV during embalming by the use of universal blood and body fluid precautions,[16] and routine immunization with hepatitis B vaccine.

ACKNOWLEDGMENTS

We are indebted to Salvatore Vitale, PhD, Barbara G. Werner, PhD, and Mary Fran McLane for their assistance in the serologic testing of the blood samples; to Margaret Nolan (Executive Director of the Massachusetts Funeral Directors' Association), Walter Hedlund (Chairman of the Massachusetts State Board of Embalming and Funeral Directing), and Nicholas Faggus for their valuable cooperation. Some of the data from this study were presented in a poster session at the APHA 116th Annual Meeting in Boston, November 13–17, 1988.

This work was supported by a Biomedical Research Support Grant No. 2S07RR05446-25 from the National Institutes of Health. Ms. Bunce Turner and Ms. Gordon also received partial support from grant no. 2 T15 OHO7096 from the National Institute for Occupational Safety and Health.

POSTDOCTORAL FELLOWSHIPS
Health Services Research Training Program
University of California

The School of Public Health, University of California, Berkeley, and the Institute for Health Policy Studies, School of Medicine, and the Institute for Health and Aging, School of Nursing, University of California, San Francisco are accepting fellowship applications for a multi-disciplinary training program in health services research.

The program is supported by the Naitonal Center for Health Services Research and Health Care Technology Assessment. It provides advanced training and education to prepare a select group of physicians and other health professionals and scholars for leadership roles in health services research.

Applications for the fellowships beginning in the summer and fall, 1990 are available now. The dealine for applying to the program is January 13, 1990; selctions will be made in March. Stipends, which range from $17,000 to $31,500, depending on years of postdoctoral experience, are governed by the National Research Service Award guidelines.

"Growing into Healthy Adults:
Pediatric Antecedents of Adult Disease"
By
Lewis H. Margolis, M.D., M.P.H., Albert W. Sparrow, M.D., M.P.H., and G. Marie Swanson, Ph.D., M.P.H.

Growing Into Healthy Adults describes childhood risks for chronic disease in adults and demonstrates how the prevention of heart disease, cancer and injuries can be viewed through a unified framework.

". . . a tour de force. . . one of the few organized compendiums about the risk factors for adult disease as found in or developed in youth."
Henry Blackburn, M.D., Director and Professor,
Division of Epidemiology, School of Public Health
University of Minnesota

"The volume and comprehensiveness of the data are wonderful. The fact that a unified approach to injury prevention, and prevention of cancer and heart disease can appear between the same two covers is a public health event worth celebrating."
Jonathon Kotch, M.D., Assistant Professor,
Department of Maternal and Child Health,
University of North Carolina at Chapel Hill

Health Care Cost Containment Measures and Mortality in Hennepin County's Medicaid Elderly and All Elderly

GREGORY L. LINDBERG, MA, NICOLE LURIE, MD, MSPH, SUSAN BANNICK-MOHRLAND, MD, ROBERT E. SHERMAN, PHD, AND PAUL A. FARSETH, BA

Abstract: In Minnesota, several health care cost containment measures occurred about the time Medicare's Prospective Payment System (PPS) was implemented. These included a moratorium on additional nursing home beds, preadmission screening of nursing home applicants, and rapid growth in HMO (health maintenance organization) enrollment by Medicare recipients. Hospital days per elderly Medicaid recipient decreased by 38 percent for those in nursing homes and by 35 percent for those not in nursing homes from 1982 to 1984. By 1986, hospital days per recipient had decreased 53 and 55 percent, respectively, from the 1982 level.

Age-adjusted mortality rates for elderly Medicaid nursing home residents for the period 1977 through 1986 showed an increasing trend after 1982. Estimated age-adjusted mortality rates for the entire County population, which had decreased steadily from 1970 to 1982, rose significantly above the projected rate in 1984, 1985, 1986, and 1987.

We conclude that, coincident with the institution of the PPS and other health care cost containment measures, use of hospital care has fallen for all elderly Medicaid recipients, age-adjusted mortality rates among those in nursing homes have increased, and the mortality rate trend for the total Hennepin County elderly population has stopped declining. (*Am J Public Health* 1989; 79:1481–1485.)

Introduction

Medicare's transition to a system of "fixed price" hospital reimbursement based on diagnosis-related groups, the prospective payment system (PPS) has triggered concerns about the consequences, particularly the chance that the poor and the chronically ill may be at increased risk of underservice.[1] At some point there is trade-off between cost and quality of care. Two manifestations of this trade-off might be an increase in age-adjusted mortality rates for Medicare patients and signs of premature hospital discharge to nursing homes.

In a cross-sectional area study of Medicare spending levels, Hadley, found that greater Medicare spending per beneficiary is associated with significantly lower mortality rates.[2] He also reported that national mortality rates for those age 65 and older have either changed little or actually increased since 1982, after declining throughout the 1970s. In Wisconsin, Sager, *et al*, reported a shift in the site of death from the hospital to the nursing home and an increase in the age-specific death rate among elderly nursing home residents from 1982 to 1985.[3] Comparing 12-month periods immediately before and after the institution of the PPS, they found a 72 percent increase in the rate of hospitalization and a 26 percent decline in hospital length of stay among elderly Medicaid nursing home patients. In a later study, Sager, *et al*, found that shifts in the location of death from hospitals to nursing homes were most pronounced in states with large declines in hospital length of stay and high population enrollments in health maintenance organizations (HMOs).[4] In a survey of nursing homes in Portland, Oregon, Lyles[5] found a 26 percent increase in the age-adjusted mortality rate among nursing home residents from 1983 to 1984. Lewis, *et al*,[6] reported that Medicare patients discharged for the first time to skilled nursing facilities in 1984 were more likely to be bed-confined, comatose, or have indwelling catheters than those discharged in 1980; however, these trends began before the institution of the PPS.

Meyer-Oakes, *et al*,[7] found a significant reduction in length of hospital stay but no change in hospital mortality post-PPS. However, they did not examine the possibility of increased post-discharge mortality. Shortell and Hughes, using 1983–84 data from 981 hospitals in 45 states found that the ratio of actual to predicted death rates for Medicare recipients with one of 16 selected diagnoses was 6 to 10 percent higher in those states with the most stringent rate reviews and 5 to 6 percent higher in those with the strictest procedures for reviewing applications for certificate of need.[8]

Fitzgerald, *et al*,[9] reported an increase in short- and long-term admissions to nursing homes after PPS for hip fracture patients in Indianapolis. Linn, *et al*,[10] have reported an increase in complication rates in patients undergoing head and neck cancer surgery after implementation of PPS.

The PPS was implemented in Hennepin County, Minnesota (the greater Minneapolis area) over a period of several months beginning in October 1983. Roughly coinciding with the implementation was the imposition of a statewide moratorium on new nursing home beds. State and county efforts to divert nursing home applicants through preadmission screening and alternative care grants were phased in beginning in 1982 and were fully implemented by 1986. The number of nursing home beds in Hennepin County has remained relatively stable over the past 10 years at around 12,000 and there has been a major increase in recent years in the provision of home health care services. For example, expenditures in Hennepin County under the state and county funded Alternative Care Grant Program increased from $200,000 in 1983 to $5 million in 1988. This represents only a small portion of the total public and private expenditures for these services. In addition, since the end of 1984, Medicare enrollees have been shifting from fee-for-service to prepaid, capitated care. As of December 31, 1986, 47 percent of all Twin Cities Metropolitan Area residents age 65 or older were enrolled in HMOs (Minnesota Department of Health, personal communication).

The present study describes changes in hospital use and

age-adjusted mortality rates that have occurred in Hennepin County following the implementation of these policy initiatives. Examined are: hospital utilization by elderly (65 and older) Medicaid recipients; the age-adjusted mortality rate for the elderly Medicaid caseload; and the age-adjusted mortality rate trend for the total elderly population in Hennepin County. The Medicaid caseload was selected for analysis because it represents a vulnerable population that is of special concern to state and local government and because health care utilization data were readily available through the Minnesota Department of Human Services. Members of this caseload differ from the general elderly population in that they are more likely to be from low income groups, may be sicker, and are more likely to have used extensive medical care or nursing home services.

Methods

Hospital Utilization Data

Data on hospital utilization by institutionalized elderly Hennepin County Medicaid recipients were obtained from the Minnesota Medicaid Information System. The Minnesota Department of Human Services provided research files containing annual client eligibility summaries and hospital payment records for the years 1980 through 1986. These included all Medicare claims in which Medicaid was a financial participant. The years, 1980 through 1982, represent a period unaffected by the PPS or local cost containment policies.

Recipients were categorized as institutionalized or non-institutionalized based on their living arrangement codes. The living arrangement code indicated the recipient's status at the last eligibility review or living arrangement change before the end of each year. Those in nursing homes or state hospitals were considered institutionalized while others were considered noninstitutionalized. During the years examined, the number of elderly institutionalized Medicaid recipients ranged from 6,800 to 7,348, and the number of elderly noninstitutionalized recipients ranged from 3,630 to 3,907. Hospital utilization and mortality rates were calculated for the full population of elderly recipients each year. There have been no major changes in Medicaid eligibility criteria or procedures from year to year that would have significantly altered the character of the caseload.

An additional analysis examined changes in hospital utilization during the last six months of life among elderly Medicaid recipients who died. Recipients selected for this analysis were those whose cases closed because of death during the last half of the year, and who had at least six continuous months of eligibility preceding their death.

The tabled hospital utilization data are presented with estimated 95 percent confidence intervals. The percentage differences in utilization between years are also presented in the text with 95 percent confidence intervals.

Mortality Data

Mortality among the Medicaid caseload was determined from annual Medicaid client eligibility files based on case closings in which death was coded as the reason for closing. To identify mortality trends over the longer term, these files were examined for 1977, the earliest year available, through 1986. Age-specific mortality rates for institutionalized and noninstitutionalized elderly Medicaid recipients were computed by five-year age intervals for each year. Age-adjusted mortality rates were then computed for these groups using, as a standard population, the mean of the age distributions for the first and last years of the time series (1977 and 1986).[11]

Age-adjusted mortality rates for the entire elderly population of Hennepin County (both Medicaid and non-Medicaid) for the period 1970–87 were derived using the death certificate data maintained by the Minnesota Department of Health and age-specific population projections developed for Hennepin County.[12] Death certificate data in Hennepin County are considered accurate and complete, and the population projections for the elderly population utilized a cohort-component procedure which is thought to result in estimation accurate to one percent or so over the study time frame. (Population estimates for the 1970–80 period were developed through linear interpolation of census data.)

Linear regression on logarithmicly transformed data was used to estimate the age-adjusted mortality rate trend during the period preceding the implementation of cost containment measures (i.e., prior to 1983). Subsequent age-adjusted mortality observations were examined to see if they fell within the 95 percent confidence interval (for observations) of the pre-cost containment trend.

Results

Changes in Hospital Utilization

There was a marked reduction in hospital days per Medicaid recipient beginning in 1983. This is due not only to a substantial reduction in average hospital length of stay, but also a large decrease in hospitalization rates (Table 1). From 1982 to 1984 (the years before and after implementation of the PPS) hospital days per Medicaid recipient per year fell 38 percent (95% CI = 32.5, 43.2) for institutionalized and 35 percent (95% CI = 26.8, 43.5) for noninstitutionalized recipients.

Hospitalization rates continued to decrease from 1984 to 1986 for both institutionalized and noninstitutionalized recipients. Length of stay decreased further as well, but at a lesser rate. The total reductions in hospital days per person for the four-year period from 1982 to 1986 were 53 percent (95% CI = 48.9, 57.6) and 55 percent (95% CI = 48.2, 62.6) for institutionalized and non-institutionalized recipients, respectively.

We also examined the change in hospital use among those recipients who died. We hypothesized that those who died would, because of the severity of their illness, experience a smaller proportionate reduction in hospital care than the general caseload. The results shown in Table 2 indicate that, from 1982 to 1984, decedents experienced percentage reductions in hospitalization that were similar to those for the general elderly Medicaid population. Total average hospital days during the last six months of life decreased by 41 percent (95% CI = 28.4, 54.6) for institutionalized decedents and by 39 percent (95% CI = 16.3, 61.7) for noninstitutionalized decedents. From 1984 to 1986, there was no significant change in this measure.

Changes in Mortality Rates

Figure 1 presents the age-adjusted mortality rate for institutionalized elderly Medicaid recipients in Hennepin County for 1977–86. The mortality rate shows an increasing trend, although the number of pre-1983 observations is small and large fluctuations that occurred in 1978 and 1979 appear out of character with other year-to-year changes. An examination of the age-adjusted mortality rates for the remainder of the state's institutionalized Medicaid caseload showed that identical fluctuations occurred in all areas of the state during

95% confidence intervals appear in parentheses.

*In this tabulation "admissions" were counted as the number of different months during which a decedent was admitted. Since a decedent might have more than one admission in a single month, these counts slightly underestimate the true admission rate, and result reciprocally in slightly overestimating the mean length of stay.

**Data needed for the calculation of this confidence interval are not available for these years.

those years, suggesting the possibility of an infectious disease epidemic. There was no consistent trend in age-adjusted mortality rates for the much smaller noninstitutionalized caseload.

To determine whether these changes were specific to the institutionalized Medicaid elderly, we also examined age-adjusted mortality rate trends in the general population of approximately 110,000 persons age 65 and over (Medicaid and non-Medicaid) in Hennepin County. Figure 2 shows that the age-adjusted mortality rates for Hennepin County elderly

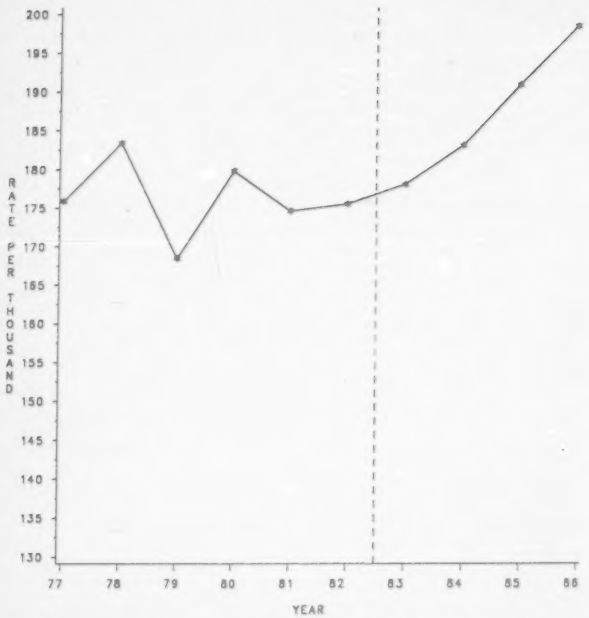

FIGURE 1—Age-Adjusted Mortality Rate, Institutionalized Medicaid Recipients, Age 65+

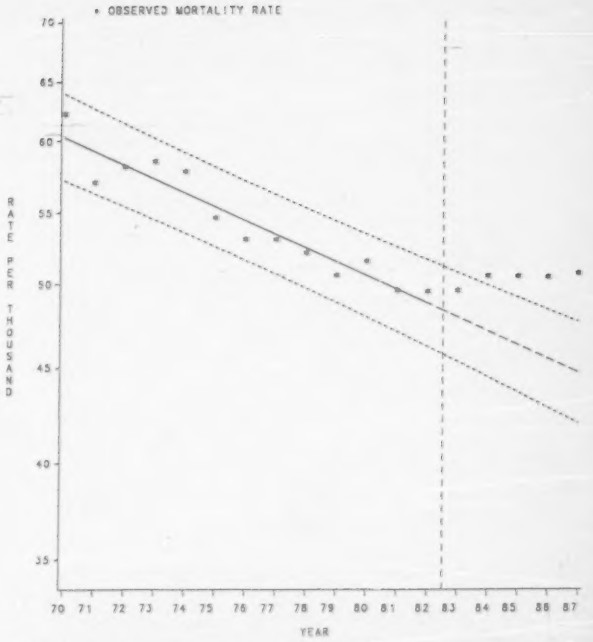

FIGURE 2—Age-Adjusted Mortality Rate for Estimated and Projected Hennepin County Population, Age 65+; Linear Regression and 95% Confidence Intervals for Years 1970–82 Projected for 1983–87

followed a roughly linear pattern of decline during the pre-cost containment period, falling from 62 per 1,000 in 1970 to 48/1,000 in 1982, a 22.5 percent reduction. Nationally, during a comparable 13-year period, 1968–80, there was a 24.2 percent reduction in age-adjusted mortality for persons age 65 and above.[13]

A linear regression line was fitted to the log-transformed 1970–82 observations to estimate the trend during the pre-cost containment period. Both the regression estimate and the 95 percent confidence interval for the pre-cost containment observations were projected through the year 1987 for comparison with observations in the post-cost containment period (1984–87). Figure 2 shows that, during 1984–87, the years following the institution of the PPS and other cost containment measures, the estimated age-adjusted mortality rates have ceased to fall and, in fact, are above the 95 percent confidence interval associated with the trend of the previous 13 years. While this does not represent an increase in the mortality rate from pre-cost containment years, it is a noteworthy departure from the mortality rate trend. It should be noted that the random variation in the mortality rate does not permit the identification of the specific year in which the mortality rate stops declining. We have selected 1983 as a break point because of the major policy changes instituted that year. Even if the break in the trend had actually begun in an earlier year, our findings of significant deviations in 1984–87 would still hold.

Discussion

These data include a large reduction in hospital admission rates and average length of stay by Hennepin County Medicaid recipients following the implementation of the PPS and other cost containment measures. The reduction in average hospital length of stay comes as no surprise. Data published in 1986 by the Health Care Financing Administration indicate that the average number of hospital days per Medicare admission to Minnesota decreased from 9.4 in 1982 to 7.3 in 1985—a 22.3 percent reduction.[14] The National Hospital Discharge Survey showed a 13.9 percent decline nationally in the average length of stay among patients age 65 and above from 1982 to 1985.[15] To a lesser extent, length of stay also declined for younger patients (11.4 percent for 45–64 year olds and 5.9 percent for 15–44 year olds). The large reduction in hospital admission rates among Medicaid recipients in our study differs from the experience in Wisconsin as reported by Sager, but is consistent with the National Hospital Discharge Survey data* and with impressions from the field that physicians have reduced their use of hospital care in response to pressure from third party payers. The reduction in days of hospital care per Hennepin County Medicaid recipient from 1982 to 1986 (53 percent for institutionalized and 55 percent for non-institutionalized recipients) far exceeds the amount one might estimate by looking only at changes in average length of stay.

The decrease in hospital care was not limited to the "healthier" members of the caseload. Recipients who died had comparable reductions in the first year following implementation of the PPS, although not in subsequent years.

Of more concern is the trend toward increasing age-adjusted mortality for the institutionalized elderly Medicaid recipients and the cessation of the downward trend in age-adjusted mortality for the general elderly Hennepin County population as a whole.

There are several possible explanations for these findings and we do not know which of them contributes most heavily. Reductions in hospital use—either decreased admis-

*The National Discharge Survey showed a decrease of 7.6 percent from 1982 to 1985 in discharges per 1,000 age 65 and older, from 428.1 to 393.2.[15]

sion rates or shorter length of stay—may have contributed to halting the downward trend in mortality rates. Changes in quality of care, including premature or inappropriate hospital discharge to nursing homes of severely ill patients or reduced intensity of appropriate in-hospital services, may also explain these findings. Both of these explanations are consistent with some of the hypothesized but unproven effects of PPS.

An alternative or contributory explanation may be the changing nursing home case mix resulting not only from early hospital discharge under PPS but from the moratorium on new nursing home beds and the introduction of preadmission screening and expanded alternative care services. By keeping less severely ill patients out of nursing homes, these programs may have the effect of increasing the severity of illness, and thus the mortality rate, in the nursing home population. While this is a plausible explanation for the increasing mortality rate in the Medicaid nursing home caseload, it does not explain the leveling of the mortality rate trend in the general elderly Hennepin County population. In addition, increased mortality rates became apparent before nursing home utilization controls were fully implemented and before the Hennepin County Medicaid nursing home caseload stopped growing (it peaked in mid-1985). The moratorium on nursing home bed construction followed the largest expansion of nursing home beds in 10 years. Full implementation of preadmission screening was not reached until mid-1986.

Finally, there have been secular changes in attitudes about appropriate levels of aggressiveness in the care of the very old and of the terminally ill. Many physicians, patients and family members now favor less intensive or heroic treatment of such patients, which may result in lowering the mean age at death and in increasing death rates in nursing homes.

Several potential limitations must be considered in interpreting these data. First, the data are from one county (albeit a very large one) and may not be consistent with trends in other areas. A preliminary examination of statewide Medicaid data has, however, revealed similar trends in nursing home mortality rates throughout Minnesota. Second, the use of case closing codes to calculate mortality rates for Medicaid recipients may introduce some error, although Hennepin County Medicaid staff were confident that the reporting of deaths is complete and accurate for those in nursing homes and there was no indication that coding practices changed over time. Third, the finding of a change in the mortality trend for the general Hennepin County elderly population is dependent upon the accuracy of the Hennepin County population projections used in the analysis. If the population projections erred on the low side, they would yield an inflated age-adjusted mortality rate. While the accuracy of the projections cannot be verified until after the 1990 census, they are thought to be reliable for the relatively stable elderly population. The projections agreed closely with other Hennepin County population projections made independently by the State Demography Unit and by the State Health Department (personal communication).[16] The substitution of those projections in our analysis would not have altered our findings.

We cannot conclude that the change in the Hennepin County mortality rate trend is caused by the policy changes we have noted, but the data are troubling and underscore the need for analyses at multiple levels. Needed first is an examination of age-adjusted mortality trends at multiple sites, controlling for differences in population characteristics, Medicaid eligibility, utilization control policies, health care resources, and the prevalence of HMO enrollment. In addition, there is an urgent need to examine the access to care and the quality and appropriateness of care received by elderly Medicare and Medicaid patients, particularly those with life-threatening or terminal illnesses, and those in nursing homes.

Prevalence of Depressive Symptoms in a Japanese Occupational Setting: A Preliminary Study

NOBORU IWATA, PHD, YUKO OKUYAMA, MD, DMSC, YOSHIKAZU KAWAKAMI, MD, DMSC, AND KAZUO SAITO, MD, DMSC

Abstract: We measured the prevalence of depressive symptoms in 2,190 Japanese tax office workers using the Japanese version of the Center for Epidemiologic Studies Depression Scale (CES-D). Score distribution by sex was more symmetrical and the mean score of each sex was higher than in the United States population. A high level of depressive symptoms was found in 15.2 percent of males and 10.6 percent of females by controlling for age and marital status. Males aged 50 years and over had more depressive symptoms than other male age groups. Perceived stress, related both to family life and the workplace, was associated with a high level of depressive symptoms. "Long-distance marriage" ("business bachelorhood"), peculiar to Japanese occupations, had little influence on depressive symptomatology. (*Am J Public Health* 1989; 79:1486–1489.)

Introduction

In industrial countries, social and workplace environments have become more complicated and stressful. Recent epidemiologic studies in the United States and some European countries have found depressive disorders to be the most common among mental disorders in the community.[1] Advances in the psychiatric epidemiology of depression include the introduction of operational classificatory schemes[2] and the application of conventional self-rating measurements to population prevalence studies.[3–6] In Japan, there are few epidemiologic studies in these areas.

Self-rating depression scale, the Center for Epidemiologic Studies Depression Scale (CES-D),[7] has been widely applied to population surveys in the US and satisfactory levels of validity and reliability have been reported.[3–14] The CES-D was translated into Japanese by Shima, *et al*,[15] in 1985. In a comparison between depressed patients and normal controls, they found that the CES-D in Japanese translation had clinical validity and that its standard cut-off point of 15/16 was appropriate for Japanese use.[15] We also found the CES-D had a good level of concurrent validity with other indices of depression and psychological distress and an acceptable level of internal reliability in a sample of Japanese workers.[16,17]

The CES-D has also been applied in several surveys of other ethnic groups,[18–23] but it has been rarely used in an occupational setting, although some studies reported the values of depressive symptomatology based on the CES-D for a subsample of the employed in the surveyed community populations.[6,8,12,14,19,24,25] In this study we present basic data on the prevalence of depressive symptomatology as measured by the CES-D in a Japanese occupational setting.

Methods

Subjects

All 2,190 workers ages 19–63 years of 29 tax offices in Hokkaido, the northern part of Japan, were asked to complete the CES-D, other psychiatric scales, and several additional questions about sociodemographic status and psychosocial factors. The survey was carried out in September 1986. Complete CES-D data were obtained from 2,016 subjects (92.1 percent; 1,870 males, 142 females, and four with sex not specified).

The subjects were approximately the same educational level (years of education = 13), stable income-earners; all were full-time employees. Few of the subjects were separated or divorced. Generally they seemed to be representative of the workers of the Japanese government offices such as the tax office, even with respect to the low proportion of female workers.

Measurements

The Japanese translated version of the CES-D[15] has 20 items rated on a four-point Likert scale ("rarely or none of the time" = 0 to "most or all of the time" = 3). A score of 16 or higher indicates a high level of depressive symptoms as used both in the United States[7–10] and Japan.[15] Each psychosocial factor was measured by one item on a five-point rating scale with response categories (and scores) from "not at all (1)" to "a large amount (5)".

Analyses

The mean CES-D score and the proportion of subjects with high level of depressive symptoms value (CES-D score

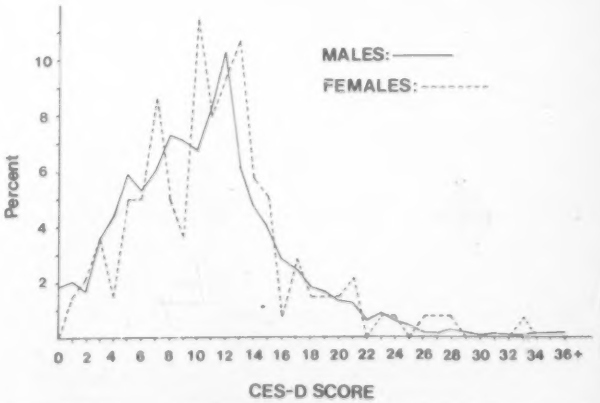

FIGURE 1—Percentage distribution of the Japanese version CES-D score by sex in a sample of Japanese workers.

of 16 or higher) were calculated by sociodemographic status and psychosocial factors. The adjusted values, controlling for the effects of age (generation) and/or marital status, were also estimated. Because there were few separated or divorced subjects, this category was combined with the "never married". Analyses were performed separately by sex.

TABLE 1—Mean CES-D Score and Percentage of the Subjects with High Level of Depressive Symptoms (CES-D score of 16 or more) among Japanese Workers Ages 19–63 Years by Sociodemographic Status and Psychosocial Factors

Adjusted values are generally estimated by controlling for sex, age, marital status, education, and income.

a) Only the results of full-time employees are presented.

b) The effect of race was also taken into account.

Results

Figure 1 displays the percentage distribution of the CES-D scores by sex. Although the distribution of females had dichotomous peaks (scores at 10 and 13) and was not artificially smoothed, there was a much smaller number of female subjects, so that the distribution of each sex was relatively similar and not heavily skewed (males: mode = 12, skewness = 1.04; females: mode = 10, skewness = 0.94) therefore standard parametric tests on these data were deemed to be appropriate.

Table 1 shows the mean CES-D score and the proportion of subjects with high level of depressive symptoms by sociodemographic status and psychosocial factors. There were no sex differences in either indicator of depressive symptomatology. When adjusted for the effect of marital status, a weak linear relationship with age was found in males. Males ages 50 years or more had more depressive symptoms than other age groups. For other sociodemographic status, both male and female subjects who were unmarried (never married or separated/divorced) and living alone had a higher level of depressive symptoms.

Among psychosocial factors, the subjects who perceived poor relationships with spouse and with parents were more depressed as were subjects who reported more stress in their family life and in the workplace. Subjects who desired medical counseling were also more depressed.

Discussion

United States studies have reported values of depressive symptomatology based on the CES-D for the employed in community populations as displayed in Table 2. Since the present results were derived from an occupational survey, they may not be comparable to the values in the table. Mean CES-D scores for both sexes were higher in our study than in the US employed, except for the Black men surveyed by Gary[14]; nevertheless the percentages of high level depressive symptoms were similar to the US employed.

One reason for the disparity of mean score between Japan and the United States may be the difference in response frequencies of the negative and positive items. The Japanese tend to choose an intermediate response to the positive items when compared to the US population so that the score distributions of the scale of Japanese subjects show generally lower frequencies than the US counterparts at the low symptom portion. Such a tendency may reflect the sociocutural and/or personality characteristics of Japanese who tend to avoid extreme answers to anything.

In Japan, many male employees have long-distance marriages (business bachelorhood, living alone separated from family members as a result of being promoted to a new job in a distant place). This situation may last for several years. Males in the subclass of the long-distance marriages were somewhat more likely to have depressive symptoms than those who were living with family members, but far less than others who were living alone.

Kessler and Essex[26] and Gove, *et al*,[27] reported that marriage had positive effects on depression and psychological well-being. The present study supports this observation; it also demonstrates that perceived stress in family life and in the workplace is related to depressive symptomatology. Worker depression has been related to such factors as work overload and job pressures in other studies.[28,29]

The limitations of the present results include the nature of the sample and the fact that each psychosocial factor is measured by a single question; a direct question about self-perceived job stress has been reported as a good predictor of subsequent ill health.[29] This should be considered a preliminary study of the mental health of Japanese workers. Further research is needed based on several samples of Japanese workers and a more thorough exploration of stress to examine the factors affecting depressive symptomatology of Japanese workers.

ACKNOWLEDGMENTS

The authors thank the club members of "Hokkaido University Wandervogel Verein" for assisting to make the dataset. We also wish to thank Dr. Carlos F. Mendes de Leon, Department of Medical Psychology, University of Limburg, The Netherlands, and Professor Eun Sul Lee, Health Science Center, University of Texas, for useful suggestion regarding the data analysis.

15th National Primary Care Nurse Practitioner Symposium: Call for Abstracts

The 15th National Primary Care Nurse Practitioner Symposium is soliciting abstracts of research, innovative clinical practice/models and roles, and other professional papers related to primary care nursing. Abstracts are being accepted for presentations or poster sessions. This symposium, the 25th Anniversary Celebration of the nurse practitioner movement, sponsored by the University of Colorado School of Nursing, will be held July 13–16, 1990 in Keystone, CO.

Preference will be given to abstracts with strong clinical applicability, innovative role development models, and papers with future-oriented perspective.

Presenters are provided tuition waiver for registration the day of their presentation but are responsible for their own travel and expenses. The deadline for abstracts is January 15, 1990.

Send three typed copies (300 words or less), format includes title, brief statement of purpose, methods, conclusions, and clinical application(s) or brief summary of project/paper if not research. Include author vita and indicate interest in presentation or poster session.

For further information, contact Ellen Lemberg, RN, MS, Box C288, Continuing Education/ Extended Studies, School of Nursing, University of Colorado Health Sciences Center, 4200 East 9th Avenue, Denver, CO 80262; (303) 270-8691.

Person-Years of Life Lost Due to Cancer in the United States, 1970 and 1984

JOHN W. HORM, MSc, AND EDWARD J. SONDIK, PhD

Abstract: The number of deaths due to cancer in the United States reached an all-time high of 453,450 deaths in 1984 and, due to the dynamics of population growth, will continue to increase if the risk of dying from cancer does not change.

Between 1970 and 1984, the total Person-Years of Life Lost (PYLL), the sum of the difference between the actual age at death and the expected remaining lifetime for each person who died of cancer, increased for most cancer sites as well as for all sites combined. In 1984, 6,881,281 person-years of life were lost due to cancer deaths, up from 5,303,668 in 1970. The exceptions are those cancers for which there has been major progress in either prevention or treatment; e.g., stomach and cervix uteri (prevention) and testicular, Hodgkin's disease, leukemia, and childhood cancers (treatment).

The Average Years of Life Lost (AYLL) per person dying from cancer in 1984 was generally less than in 1970. Overall, each person who died from cancer in 1984 died 15.2 years earlier than his/her life expectancy. The greatest loss was for those who died of childhood cancers (66.9 years earlier), followed by testicular cancer (35.8 years earlier). The least loss relative to the expectation of life was for those who died of prostate cancer. The 25,400 men who died from prostate cancer in 1984 died an average of nine years earlier than otherwise expected. (*Am J Public Health* 1989; 79:1490–1493.)

Introduction

Deaths due to cancer accounted for 453,450 deaths in 1984[1] in the United States, second only to heart disease. Many of these deaths may be postponed or avoided entirely through the use of appropriate interventions such as primary prevention, screening/early detection, and increased application of state-of-the-art treatment.[2] A death which occurs before the end of average life expectancy is, by definition, a premature death. The age-adjusted and age-specific cancer mortality rates do not fully address the issue of premature mortality and therefore other measures are needed.[3]

Person-Years of Life Lost (PYLL) considers a cancer death to be premature in that the death occurred earlier than it would have occurred in the absence of that cancer.

Average Years of Life Lost (AYLL) is the average of the differences between the actual ages at death and the expected remaining years of life for each person who died of cancer.

In our computation of PYLL and AYLL we have used age-based and sex-specific estimates of the length of life remaining rather than fix an upper bound on length of life at age 65 such as has been used by others.

Taken together, the PYLL and the AYLL reflect the cost of dying from cancer in terms of lost years of life expectancy. They may also be used to assist in the evaluation of cancer control progress and to provide guidance for resource allocation in cancer prevention and control. We examined PYLL and AYLL for cancer in 1970 and 1984.

Methods

The numbers of cancer deaths for both 1970 and 1984 and information on the underlying cause of death as well as demographic information such as age, sex, race, and other items for each death occurring annually in the United States were obtained from the National Center for Health Statistics (NCHS). The deaths have been categorized by anatomic site of the cancer, sex, and age at death for each calendar year.

Address reprint requests to John W. Horm, MSc, Statistician, Special Populations Studies Branch, Division of Cancer Prevention and Control, National Cancer Institute, EPN-240, 9000 Rockville Pike, Bethesda, MD 20892. Dr. Sondik is Acting Associate Director, Cancer Control Sciences Program, DCPC, NCI. This paper, submitted to the Journal November 9, 1988, was revised and accepted for publication May 9, 1989.

For each cancer death which occurred in either 1970 or 1984, the PYLL was estimated by taking the difference between the actual age at which the person died and the expectation of remaining life for an individual matched by age and sex for each of 1970 and 1984 as obtained from life tables published yearly by the NCHS.[5,6] These differences were then summed over all persons dying of cancer for 1970 and for 1984.

The AYLL is a statistical average arrived at by simply dividing the total PYLL by the number of people affected. From Table 1, 4,564 women died prematurely from cancer of the cervix uteri in 1984 for a total of 105,899 person-years of life lost or an average of 23.2 years of life lost for each of the 4,564 women.

Results

Tables 1, 2, and 3 have for both 1970 and 1984 the numbers of cancer deaths in the United States, the total number of person-years of life lost due to cancer, and the average years of life lost for those who died of cancer. The cost in average years of life lost was greater for women (17.1) than for men (13.5) in 1984, due in part to the greater life expectancy for women compared to men, 78.2 years and 71.2 years, respectively. Even though there were fewer women than men dying from cancer in 1984 (210,687 versus 242,763), the women lost more potential years of life, 3.6 million compared to 3.3 million for men. For both sexes combined, lung cancer caused the loss of the most total person-years of life in 1984 followed by breast and colorectal cancer (Figure 1). Deaths due to testicular cancer, because of the small numbers of deaths, cost the fewest total person-years of life among those cancer sites investigated.

In contrast, the greatest average years of life lost per person dying of cancer was for childhood cancers (Figure 2), followed by deaths due to testicular cancer, Hodgkin's disease, cancer of the cervix uteri, brain cancer and finally malignant melanoma, each of which caused death more than 20 years before the life expectancy.

In 1984 the most costly cancer for women was cancer of the breast which caused a loss of over 760,000 person-years of life among 39,470 women, up 28 percent from 1970. These women died an average of 19.3 years earlier than expected. Mass screening programs have suggested that the mortality

from breast cancer can be reduced by 30 percent through screening.[7,8] If so, a screening program could prevent about 11,800 breast cancer deaths per year. If these 11,800 women were to live to their full life expectancy, about 227,000 person-years of life could be saved yearly.

The 36,180 women who died from lung cancer in 1984 lost a total of 643,889 person-years of life, almost triple the 1970 figure of 238,254 person-years. In 1984, these women died an average of 17.8 years before expected, an improvement over 1970 when female lung cancer victims died 19.3 years before their life expectancy. It is believed that about 75 percent of lung cancer deaths among women are caused by cigarette smoking.[9] Preventing 75 percent of these lung cancer deaths could result in the postponement of death by some 19 years for over 27,000 women annually. This would result in the saving of over 500,000 person-years of life every year.

Additionally, 75 percent of the deaths due to cancer of the cervix uteri are thought to be preventable through screening with the Pap smear.[10] Pap smear screening could potentially extend the lives of 3,400 women by 23 years each for a total savings of 78,200 person-years of life.

Dramatic improvements have been noted in the person-years of life lost among women between 1970 and 1984 for Hodgkin's disease with a 44 percent decrease and, most dramatically, childhood cancers with less than half as many person-years of life lost in 1984 than in 1970. Smaller decreases are seen for cancers of the stomach and for

leukemias.

Among men, lung cancer was the most deadly cancer causing the loss of the most person-years of life in 1984. Over 1.1 million person-years of life were lost among 82,385 men who died of lung cancer an average of 13.5 years earlier than otherwise expected. If 80 percent of these deaths could be avoided through prevention, almost 900,000 person-years of life could be gained annually.

Colorectal cancer deaths accounted for 338,649 lost person-years of life in 1984, up by 26 percent since 1970. Each man who died from colorectal cancer in 1984 died, on the average, 12.1 years before he would have otherwise expected to die.

Deaths from prostatic cancer among 25,400 men cost almost 229,000 person-years of lost life in 1984 as these men died nine years before their average life expectancy would predict.

Five cancer sites among those examined actually demonstrated decreases in the number of person-years of life lost due to cancer deaths between 1970 and 1984. Both testicular and childhood cancer had decreases in the person-years of life lost of about 45 percent from 1970 to 1984 amounting to

a savings of 69 thousand person-years of life in 1984 alone. The improvement in testicular cancer is primarily due to the development of curative chemotherapy for nonseminoma cases which has increased the five-year survival rate to over 80 percent.[14,15] Although testicular cancer is relatively rare, it causes death an average of 35.8 years before the normal life expectancy. Male childhood cancer victims died 63.6 years earlier than expected in 1984 with 68,257 person-years of life lost among 1,073 boys. Additional savings are seen for Hodgkin's disease, a 38 percent improvement; stomach cancer, an 11 percent improvement; and a 4 percent improvement for leukemia.

Discussion

The methodology used here differs from that used in previous investigations in that here we have used the life expectancy as the endpoint rather than age 65.[11–13] We believe that the life expectancy is a more appropriate endpoint for such an analysis because a large proportion of cancer deaths, about 65 percent, as well as 70 percent of non-cancer deaths occur over the age of 65 and today people remain productive and active well beyond the classical retirement age of 65. Further, we would argue that any death which is either preventable or avoidable, and which occurs before the end of the affected person's normal lifespan, is premature and hence should contribute to person-years of life lost. It should be noted that in 1984, a person 65 years old could expect to live for another 16.8 years.

The PYLL and AYLL are estimates of the differences between the actual age at death and the expected age at death considering all possible causes of death weighted by their occurrence in the population at large. These estimates do not depend on the date of diagnosis nor on the time between diagnosis and death (survival) and thus are free of some of the problems inherent in the interpretation of trends in incidence and survival rates due to diagnostic artifacts such as lead time bias.

Ideally we would like the PYLL to decrease over time. However, due to the aging of the population and to the increasing size of the population and therefore the greater numbers of persons at risk of death from cancer, it is possible for the PYLL to increase without an increase in the age-sex-specific risk of dying of cancer. The PYLL then estimates the actual impact of the cancer deaths on the population in terms of total person-years of life lost every year. As the impact of competing causes of death on the population lessens, the PYLL due to cancer will continue to become numerically larger in the United States for the reasons outlined above.

On the other hand, the AYLL (Average Years of Life Lost) estimates the joint effects of the changes in the cancer patients' ages at death and the change in the population life expectancy. The life expectancy at birth of the United States population increased by almost four years between 1970 and 1984, from 70.9 to 74.7, respectively. The expectation of remaining life also increased between 1970 and 1984 for all races combined, for each sex, and at every age with larger increases for younger persons and lesser increases for older persons. For making comparisons over time, we can artificially hold the overall life expectancy constant. In so doing, the comparison of two AYLLs shows the change in the average loss of expected life-years per cancer death.

It is important to note that the AYLL is based only on those people who die from cancer and therefore does not provide an estimate of either cure or prevention. For example, the number of people dying from testicular cancer decreased from 760 in 1970 to 401 to 1984 due to the advent of curative treatment but the AYLL increased because of different age and stage distributions between those who died and those who were cured. We also note that with no change in cancer patient survival, the AYLL would be expected to increase in accordance with the increasing life expectancy of the United States population. Therefore, we consider any changes in AYLL as a conservative (pessimistic) estimate of the curative life extension impact of cancer treatment.

Breast Cancer Risk and Participation in Mammographic Screening

STEPHEN TAPLIN, MD, MPH, CAROLYN ANDERMAN, MPH, AND LOUIS GROTHAUS, MA

Abstract: Within the context of an organized breast cancer screening program we conducted a prospective evaluation of the relation between breast cancer risk and participation in mammographic screening. The influence on participation of known breast cancer risk factors, as well as a summary risk label, (i.e. "high", or "moderate") were examined. The overall participation rate was 71 percent among 2,422 women, 50 to 79 years of age, invited to a centralized clinic. Multivariate analyses showed participation to be somewhat decreased among women with late menopause and definitely increased among women with any of the following factors: 1) increased age; 2) a family history of breast cancer; and 3) a previous breast biopsy. Women in the high-risk group were most likely to participate but the effect of the label was stronger among women ages 50 to 59 compared to women ages 60 to 79. The study results are generally consistent with previous findings that participants in screening programs have higher rates of breast cancer. The results also suggest the possibility that providing breast cancer risk information may encourage participation in screening. (*Am J Public Health* 1989; 79:1494–1498.)

Introduction

Self-selection bias has been a major concern in the assessment of cancer screening modalities.[1–3] The Health Insurance Plan (HIP) randomized trial of mammography demonstrated that breast cancer rates were higher among women who complied with an invitation to obtain a mammogram (participants) compared to those in the study population who did not comply with that invitation.[4] Several investigators have shown a higher prevalence of breast cancer symptoms among participants, but the influence of breast cancer risk factors on screening behavior has not been thoroughly evaluated.[5]

Investigators have examined the relationship between women's use of mammography and three risk factors: age, family history, and previous benign breast disease.[5–10] All but one of the studies were conducted retrospectively.[7] Participation appears to decrease with advancing age,[5–7] although one report showed increased participation,[8] and yet another found no association.[9] Two studies found no association between family history and participation.[5,6] A third study reported that participants in screening were more likely to have a family history of breast cancer, but this finding was based on very small numbers.[9] One study has examined the role of previous benign breast disease and showed an association in a negative direction with subsequent participation in screening, but the definition of this disorder was not explicit.[9]

The study reported here prospectively evaluates the association between participation in an organized screening program and the following six risk factors: age, family history of breast cancer, having a previous benign breast biopsy, nulliparity to age 30, early age at menarche, and late age at menopause. Previous work has suggested that perceived vulnerability to breast cancer is positively associated with participation in screening.[5,7,8] We, therefore, hypothesized that those factors which might be readily identified by a woman as increasing her risk of breast cancer (i.e., increased age, family history, and having needed a breast biopsy) would show positive associations with participation in screening. In contrast, we expected that nulliparity, early age at menarche, and late age at menopause would not be associated with participation in screening, as women are less likely to be aware that these factors increase their risk for breast cancer. In addition to the association between specific risk factors and participation in screening, this study also assessed the effect of being informed that one is at high risk vs moderate risk for breast cancer.

Methods

The study was conducted at Group Health Cooperative of Puget Sound (GHC), a 360,000-member closed panel health maintenance organization (HMO) that includes two hospitals and 21 primary care facilities in Western Washington state. Women GHC enrollees are slightly better educated and more likely to be in households with higher incomes than the general population of comparably aged women residing in Washington state.[11]

In March of 1985, Group Health Cooperative initiated a risk-based Breast Cancer Screening Program.[12,13] All female enrollees 40 years of age and older were mailed a two-page questionnaire which elicits information concerning breast cancer risk factors, medical and screening history, and selected lifestyle behaviors. Seven of 21 items on the questionnaire pertain to specific breast cancer risk factors. The response rate to this survey has been 85 percent.[13,14] Based on their personal constellation of risk factors, all women are assigned by the screening program to one of four risk categories: "high," "moderate," "borderline," or "no increased risk" which represent 18, 27, 12, and 43 percent of the population, respectively (see Appendix). Each woman who completes and returns this questionnaire is sent a follow-up letter, within two months, which indicates her risk category and a recommendation to: perform monthly breast self-examination, obtain a breast physical examination annually, and be seen in the breast cancer screening center for a mammogram every 1, 3, or 5 years according to risk level. Letters of invitation do not convey any risk factor information other than a woman's risk category. An automated data system maintains the survey data and documents all screening activity. These data served as the basis for the analysis of participation presented here.

The sample for this analysis consisted of women who had completed a risk factor questionnaire, were invited for a screening visit between March 1, 1985 and December 31, 1985, reported no mammogram during the one year prior to

© 1989 American Journal of Public Health 0090-0036/89$1.50

being surveyed, and were continuously enrolled at GHC since being invited to come in for screening. The study group was limited to women ages 50 to 79 who were in the "high" and "moderate" risk categories (Table 1). Of the 2,722 women in this group, 2,422 received invitations to the screening program during this period and constitute the study population. The non-study population consists of the 300 women from this group who did not receive invitations during the study period plus 4,498 women whose only risk factor was age. At the time of this study, these women were placed in a group designated as "no increased risk" and were not invited for a screening visit. This policy has subsequently changed.[13]

Participation was defined as scheduling and completing an appointment in the screening center by June 30, 1986. There was no fee for this visit which included instruction in breast self-examination and a physical examination of the breast, as well as the mammogram. Subjects had a minimum of six and maximum of 15 months opportunity to come in for screening following their invitation. At the time of this study, the wait time to obtain a mammogram was approximately one month. Analysis of overall program data shows that 93 percent of women who participate within one year do so within the first six months after being invited. Women received only one invitation and were not sent any reminders.

The relation between participation in screening and the following six factors was considered: age, family history of breast cancer, previous benign breast disease, menarche at 10 years of age or younger, menopause at 55 years of age or older, and nulliparity to age 30. A positive family history was defined as having one or more first or second degree family members with a history of breast cancer (i.e., mother, sister, daughter, grandmother, or aunt). Benign breast disease was defined as having reported one or more breast biopsies which were non-cancerous. In addition to considering the six individual risk factors, the effect on participation of being assigned a "high" vs "moderate" risk label was examined.

Bivariate contingency table analyses were carried out initially to assess the association between participation and each of the seven variables considered individually. Logistic regression was then used to estimate the effect of each variable controlling for the influence of all others. The logistic analysis was done in two steps. First, models were fit to test if there were any significant interactions between risk label and the other variables. Then, a final logistic model was fit containing the seven main effects plus any significant interactions.

TABLE 1—Risk Factor Comparison in Study vs Non-Study Women

[a]Among GHC women 50 years of age and older who completed and returned a risk factor questionnaire before December 31, 1985 and had not reported having a mammogram within one year. "Study Women" are those women who were invited for screening; "Non-Study Women" represent those who were not invited by December 31, 1985.
[b]There are no "Borderline" risk women in the age group studied (see Appendix).
[c]These women have none of the risk factors listed, except age.

Results

Since the study population was composed of women who were invited for screening because they were at increased risk for breast cancer, each woman necessarily had one or more risk factors for the disease. As expected, a higher proportion of study women had any given risk factor compared to non-study women (Table 1).

Table 2 shows the percentage of study women with each of the six risk factors according to their risk category. As expected, a larger proportion of high-risk women have any particular risk factor.

Of the 2,422 women in the study population, 71 percent came in to the screening center as requested by the letter of invitation. Table 3 shows the crude odds ratios (OR) for the association between breast cancer risk factors and participation in mammography. The strongest association is between the risk category and participation (OR = 2.59), followed by family history (OR = 1.83), previous biopsy (OR = 1.60), and age (OR = 1.45). Age is dichotomized in this bivariate analysis since participation varies little among women above age 60 when grouped into five-year intervals (73 percent to 75 percent). Three factors (age ≥ 55 at menopause, nulliparity to age 30, and age ≤ 10 at menarche) show no association with participation.

Table 4 shows odds ratios estimated from the logistic regression analysis. Since there is a significant interaction between age and risk designation, the final logistic model consists of the six risk factors, the risk designation, and this interaction term. Family history of breast cancer and previous benign breast biopsy continue to be associated with increased participation although the odds ratio is slightly less. Neither nulliparity to age 30 nor menarche at age 10 or

TABLE 2—Proportion of Women in Moderate and High-Risk Categories Who Have a Particular Risk Factor

Risk Factors	Risk Category[a]	
	Moderate (N = 1547)	High (N = 875)
Age 60–79 years	61%[b]	66%
Family History of Breast Cancer[c]	21%	63%
Previous Benign Breast Biopsy	15%	37%
Nulliparity to Age 30	31%	43%
Age ≤ 10 at Menarche	5%	10%
Age ≥ 55 at Menopause	14%	24%

[a]Risk category is the designation given by the screening program according to the algorithm in the Appendix.
[b]For example, 61 percent of moderate-risk women are 60 to 79 years of age compared to 66 percent of high-risk women.
[c]First and second degree family history result in different risk designations (see Appendix).

TABLE 4—Results of Logistic Regression Analysis of Breast Cancer Risk and Participation in Mammographic Screening

Characteristics	Adjusted Odds Ratio[a]	(95% CI)
Family History Breast Cancer	1.35	(1.02, 1.79)
Previous Benign Breast Biopsy	1.36	(1.02, 1.81)
Nulliparity to Age 30	0.97	(0.75, 1.24)
Age ≤ 10 at Menarche	0.82	(0.55, 1.22)
Age ≥ 55 at Menopause	0.73	(0.55, 0.97)
Age and Risk Category[b]		
Moderate Risk Category		
Age 50–59	1.00	
Age 60–79	1.86	(1.49, 2.32)
High Risk Category		
Age 50–59	3.94	(2.61, 5.96)
Age 60–79	3.09	(2.21, 4.31)

[a]Odds ratios estimated from the logistic regression model including all six risk factors and a variable for the interaction between "age" and "risk category." Odds ratios are defined so that those without the characteristic are the reference group.
[b] Odds ratios are defined so that women ages 50–59 who are at "moderate" risk are the reference group.

younger show any association with participation. Controlling for other risk factors in the multivariate model increased the association between late menopause and participation.

The association of age with participation depends on whether the risk label was "moderate" or "high." Increasing age is associated with participation only among women with the "moderate" risk label. For women labeled high-risk, participation is essentially the same or even slightly less among older women (OR = 3.09/3.94 = 0.78).

As seen in the bivariate analysis, the high-risk label shows the strongest association with participation. However, the four odds ratios for the joint factors in Table 4 reveal that the association between the high-risk label and participation was more than two times as strong in younger (OR = 3.94) compared to older women (OR = 3.09/1.86 = 1.66, Table 4).

Discussion

The results of this study substantiate our hypothesis that risk factors recognizable by lay persons such as age, family history, previous benign breast biopsy, and the high-risk label are each positively associated with compliance with a mailed recommendation to obtain a screening mammogram. Since risk factor information was collected prior to screening visits, recall bias was avoided. The prospective observation of the entire population in the course of their usual care also eliminates any Hawthorne effect created in the process of selecting and observing a separate study population.

Performing the study in the context of a formal screening program also creates some potential limitations. First, all candidates for the study were respondents to the screening survey; the relation between risk and participation might be different for non-respondents. However, since 85 percent of women complete the risk factor questionnaire, this potential threat to generalizability is expected to be minimal. Second, as a result of the screening program's design, all study women had at least one risk factor in addition to age. In considering each individual risk factor, the referent group consisted of women without any factor but possessing "other" risk factors. While it is not possible to determine from these data whether the magnitude of the associations might differ substantially if the referent population included women whose only risk factor is age, it is likely that the associations would be stronger.

A final limitation is that the results may be biased due to residual confounding by two factors. The first is socioeconomic status (SES) for which no data were available. Since higher socioeconomic status has been associated with increased risk of breast cancer[15] and with increased participation in screening,[5,7] it must be considered a potential confounder. However, any effect of SES would be expected to be small since GHC is somewhat more homogeneous with respect to SES compared to the surrounding SMSA population.[11] Second, there may be residual confounding due to the presence of breast cancer symptoms. Participants in the HIP study were more likely to report pre-menstrual breast tenderness or having previously felt a breast lump.[5] However, when women call for an appointment at the GHC screening center, the policy is to ask about pain, lumps, or the presence of nipple discharge. Women with any of these symptoms are advised to see their primary care physician, so it is expected that the majority of screened women were asymptomatic. Symptomatic women who called for an appointment and were referred to their physician would have been misclassified as non-participants in this study since the program does not document these calls in its automated data base. This misclassification would weaken the observed associations.

Our data show that family history of breast cancer is significantly associated with participation even after controlling for other risk factors. French's work found that participants were more likely to have a family history of breast cancer than non-participants, but the difference was not statistically significant.[9] In the HIP study, there was no significant difference in "family history of cancer" between women who completed all four screening examinations compared to those who did not.[5] However, that study did not evaluate the relationship between family history of breast cancer and participation.

Our finding of increased participation among older women is not consistent with previous reports which show

associations in the opposite direction.[5–7] However, none of these studies included women beyond 64 years of age and only one was conducted prospectively.[7] The data presented here suggest women 60 to 79 years of age are more likely to participate than women 50 to 59 years of age. While the reason for lower participation in younger women is not clear, one possible explanation is that these women are more likely to be employed and therefore have conflicts during usual screening clinic hours.

Our finding of increased participation in older women is important because more women are living longer and the incidence of breast cancer increases greatly with advancing age. Celentano has pointed out that primary care providers often fail to offer cancer screening procedures to the elderly.[16] Others have suggested that cost is a barrier.[17,18] The relative importance of these two factors is not clear. With the advent of Medicare coverage for mammography every two years, it will be important to observe whether the use of mammography increases among older women in other populations. Our data suggest that senior women will use mammography if it is offered to them, and cost is not an issue.

No other studies to our knowledge have examined the association between participation and the three other risk factors studied here: nulliparity to age 30, early age at menarche, and late age at menopause. Our findings are not completely consistent with our hypothesis that these factors would be unassociated with participation. No associations exist in the bivariate analysis. However, after controlling for all other risk factors in the multivariate model, a negative association appears between late menopause and participation. The explanation for this is not clear, but one consideration is that there is confounding by some other factor such as estrogen use. This relation needs closer examination in future studies.

The increased participation among women with particular risk factors that is demonstrated in this study is consistent with the Health Belief Model[19,20] which suggests that perceived vulnerability to disease should influence the likelihood that a person will undertake preventive behaviors. We hypothesized that women with certain risk factors would be more likely to perceive themselves as vulnerable, and therefore participate in screening. While the increased participation has been demonstrated with our data, we did not directly evaluate women's perception of their vulnerability.

The risk assessment/feedback process used in Group Health Cooperative's Breast Cancer Screening Program is similar to Health Risk Appraisal (HRA) and may be a way to increase the use of mammography. The HRA process provides individuals with quantitative and/or qualitative disease risk estimates based on self-reported risk factors obtained through questionnaires.[21] Proponents of HRA argue that it is an effective strategy for facilitating positive health-related behavior. Our finding that women given a high-risk designation were most likely to participate suggests that this may be true. However, more needs to be learned about the effect of different risk labels, and the influence of these designations on other behaviors. Experience from hypertensive labeling suggests that there are potential negative effects such as increased depressive symptoms, and lower self-perceived health.[22]

In conclusion, overall our study found the expected positive associations between participation and those risk factors that could be easily identified by women. Self-selection for screening by women at increased risk has been identified as a major concern in the non-experimental evaluation of screening.[1–3] Our findings give substance to these concerns but also raise the possibility that informing women of all their risk factors or using a summary risk label may take advantage of the motivation behind self-selection and encourage participation.

APPENDIX
Risk Algorithm*

High-Risk Group	• Previous breast cancer • Mother with breast cancer • Age 50+ and 2 VRF listed below
Moderate-Risk Group	• Age 40–49 and 2 VRF listed below • Over age 50 and 1 VRF listed below
Borderline Risk	• Age 40–49 and 1 VRF listed below
No Increased Risk	• No VRF, any age
Variable Risk Factors (VRF)	• Previous cancer (other than breast) • First or Second degree relative (other than mother) with breast cancer • Menarche age 10 or under • Nulliparity • 1st pregnancy age ≥ 30 • Menopause age ≥ 55 • Previous benign breast disease

*Risk algorithm used in Group Health Cooperative's Breast Cancer Screening Program until April 1988.[13]

RWJ Foundation Awards Grant to Study Child Abuse Responses in 50 States

The first 50-state survey of child abuse policies and regulations will be launched by the American Bar Association (ABA) with a grant from the nation's largest health care philanthropy. The $280,464 two-year grant has been awarded to the ABA Fund for Justice and Education from the Princeton-based Robert Wood Johnson Foundation. The ABA, in conjunction with the American Academy of Pediatrics, will develop recommendations about policies and procedures related to prevention, intervention, and investigations of child abuse.

Under the direction of Susan J. Wells, PhD, the ABA survey will gather and analyze information from child welfare agencies, physicians, coroners, police officials, prosecutors, and legislators in all 50 states to determine how state and local governments are currently responding to child abuse.

It is estimated that child deaths from abuse have increased 34 percent since 1985, resulting in about 5,000 deaths a year, said Leighton E. Cluff, MD, Foundation president. "But because states don't collect child abuse data uniformly, there is little information to guide policymakers and other officials working to prevent these deaths," he added. Cluff termed the ABA project "an important first step" in addressing the problem and in understanding the effect of interventions intended to prevent child abuse.

In addition to collecting data, the ABA will provide consultation to selected states that have expressed interest in revising their policies regarding child abuse.

The Robert Wood Johnson Foundation was established as a national philanthropy in 1972. Since then, it has awarded more than $996 million in grants to improve health care for such US populations as adolescents, children and mothers, the elderly, the homeless, the mentally ill, people with AIDS, and the uninsured. For further information, contact the RWJ Foundation, PO Box 2316, Princeton, NJ 08543-2316. Tel: (609) 452-8701.

Breast Cancer Screening by Mammography: Utilization and Associated Factors

JANE G. ZAPKA, ScD, ANNE M. STODDARD, ScD, MARY E. COSTANZA, MD, AND HARRY L. GREENE, MD

Abstract: The status of mammography screening experience and factors related to utilization were examined in six towns serviced by physician staffs at five hospitals. Data were collected via random digit dial telephone interview of a probability sample of 1184 women, aged 45–75 years. The results showed that 55% of the women reported ever having had a mammogram. Of those who had ever had a mammogram, 21% reported that the mammogram in the past year was their first one. Of those women who are over 50 and had ever had a mammogram, 57% reported one in the past year. Analyses demonstrated that a combination of demographic factors, certain beliefs and knowledge, having a regular physician, social interaction and media exposure are independently related to ever having a mammogram, and to having one in the past year. Despite anecdotal and empirical evidence that the proportion of women ever having had a mammogram has substantially increased in the past several years, increasing utilization among older and lower-income women provides a challenge for public health (*Am J Public Health* 1989; 79:1499–1502.)

Introduction

Among women, breast cancer leads all other cancers (28% in women), and is the second leading cause of cancer death.[1] Reductions in mortality from breast cancer depend on successful interventions aimed at early detection and treatment,[2–4] but the adoption of screening technologies by physicians and women has been slow.[5–7] However, there are recent indications that the utilization of screening technologies, notably mammography, has been increasing.[8] Targeted interventions are being called for by medical and public health authorities.[4,5] This study was undertaken to characterize the breast cancer screening experience, knowledge, and attitudes of a probability sample of urban women so as to provide a valid base for planning community interventions aimed at increasing the appropriate use of screening technologies.

Methods

A survey was conducted using the Waksburg random digit dial method[9] in two urban areas of eastern Massachusetts comprising six towns serviced by physician staffs of five community hospitals. A pretested structured 20-minute telephone interview was administered in late 1987. A woman was eligible for the study if she was between 45 and 75 years of age and had never had breast cancer. A minimum of 10 call-backs were made as needed to secure an interview, and a refusal conversion process was included. A response rate of 75.3 percent was achieved, yielding a sample of 1,184 women.

In addition to sociodemographic and health history items, the survey included items to measure knowledge (such as risk factor and incidence knowledge and knowledge that mammography is appropriate in the absence of symptoms), beliefs (such as perception of barriers to and benefits of having a mammogram, and susceptibility to breast cancer), enabling factors (insurance coverage, having a regular physician and usual location of care) and factors which reinforce or hinder screening behavior (encouragement to have screening by family, friends, and providers, discussion about screening with social network members and exposure to media messages about breast cancer screening). Summary variables were computed for items purported to measure personal and social factors and tests of reliability yielded Cronbach's alpha coefficients in the range of .56 to .71.*

We first looked at variables associated with ever having a mammogram in the total sample. Among women who had a previous mammogram, we subsequently looked at correlates of having a mammogram in the last year for those aged 50 and over. While recent study results suggest reduction in mortality from breast cancer with mammography in younger women,[10] the issue remains controversial. Therefore, women under age 50 were removed from this analysis since current guidelines do not consistently recommend annual screening for women under age 50.

For this exploratory study, forward stepwise logistic regression analysis[11] was used to select from among those bivariately associated with screening, a set of variables representing independent correlates of screening behavior. After main effect variables were entered into the model, selected two-way and higher order interactions were considered. The entry criterion was a chi-square p value of 0.05. Some interactions could not be tested due to sparse cells in the relevant multiway cross classifications.

Results

Selected characteristics of the sample are presented in Table 1. Fifty-five percent of the 1184 women surveyed reported ever having a mammogram. Among the 45 percent who had never had a mammogram, 10 percent had never heard of mammography. Twenty-five percent of the total sample reported previous medical problems with their breasts and these women were significantly more likely to have had multiple mammograms than those who reported never having had a problem. However, the majority of women (82 percent) reported having had their mammogram as a "check-up, for no particular problem." Women who had less than a high school education, or were Catholic or

Widowed	211	46.9 (99)	25.8 (51)
Never married	43	48.8 (21)	42.4 (14)
Ever had medical problem with breast			
Yes	292	83.6 (244)	43.6 (98)
No	892	45.5 (406)	27.0 (192)

[a]Frequencies may not sum to total sample due to missing data in respective cross-tabulations.
[b]For women over 50 years of age.

Protestant (as compared to Jewish), were significantly less likely to have ever had a mammogram or had one in the past year. Income was directly related to ever having a mammogram; education and employment were highly correlated with income for the 86 percent of subjects who responded to the income question.

Given that getting a mammogram requires interaction with the medical care system, we were particularly interested in several variables related to sources and perceptions of medical care as well as insurance variables. Eighty-five percent of women reported that they had a regular physician. A majority (74 percent) of those who had a mammogram had had a clinical breast examination in the last year vs 44 percent of those who had never had a mammogram. Seven percent of the sample did not have any level of health insurance or entitlements. Seventy-one percent of those who ever had a mammogram said their insurance paid for it, 10 percent paid for it themselves, and 16 percent reported some combination.

Women who had never had a mammogram were asked why. Forty-five percent responded that they did not feel it was necessary and/or that they felt healthy, and 24 percent said their doctor had never recommended it. All women were asked if they would have a mammogram in the next year if their doctor recommended it, and 83 percent said they were very certain they would.

Factors Associated with Mammogram Experience

Table 2 presents the results of the main effects logistic regression analysis on ever having had a mammogram. There were significant negative interactions (data not shown) between being encouraged by a friend to have a mammogram and disagreeing with the statement that symptoms should precede a mammogram, and between being encouraged by a friend and discussing mammography with a friend. These interactions indicate that once one event has occurred there is no additional association with the other event. Variables which showed bivariate associations with ever having had a mammogram but which did not enter the model include knowledge of breast cancer risk factors, perceptions of susceptibility to breast cancer, perception of barriers to mammography, a belief that other health problems have priority, and education attainment. Women whose regular physician was an internist or gynecologist were more likely to report ever having a mammogram than women whose physician was a general or family practitioner (68 percent vs 41 percent); the latter women were no more likely to have had a mammogram than women with no regular doctor.

The women age 50 and over who had ever had a mammogram were divided into those who had one within the past year and those who had not. The main effects logistic regression model for this comparison is given in Table 3. Although having a mother or sister with breast cancer was positively associated with ever having a mammogram, having another relative (e.g., aunt) with breast cancer was negatively associated with having one in the last year. Variables which showed bivariate associations with mammography in the last year but which did not enter the model include a belief that mammography can detect cancer, history of breast problems, and employment status.

We were interested in the impact of insurance coverage on mammogram experience. Reliable and valid information on coverage was limited. A substantial number of subjects reported having more than one type of coverage. Since it was not possible to determine which plan provided coverage,

women with more than one type of coverage were excluded and the screening behavior of those women who reported only one type of coverage was further examined. Given the possibility that a person's insurance plan changes over the years, analysis was limited only to mammogram experience in the past year. Bivariate analysis demonstrated that 34 percent of women who had commercial insurance, health maintenance organization (HMO) or Medicare plus commercial insurance had a mammogram in the past year compared to 15 percent of women covered by Medicare only, Medicaid only, or no insurance. For this set of subjects, the insurance variable did not significantly improve the multiple logistic model.

Discussion

The findings of this study support anecdotal and empirical evidence that the proportion of women ever having a mammogram has substantially increased in the last several years, particularly among White, middle and upper socioeconomic level, and younger women.[5,8,12] Further, we found that although a greater proportion of women over age 60 have never had a mammogram, among those who have ever had one, more older women than younger women did get one in the past year. A summary of data from 33 states[13] reported that 29 percent of US women 50 years of age or older reported having had a screening mammogram in the last year. The level of screening varies considerably by state, however, with 37 percent reported in Massachusetts.[14] For our sample of women ages 50–75 years, 31 percent reported a mammogram in the past year.

It is very difficult to determine the extent to which women have had mammographic examinations for screening rather than diagnostic purposes.[5] Our data demonstrate a positive correlation between previous breast problems and having had one mammogram or having multiple mammograms. However, 82 percent of the women reported that their most recent mammogram was for "check-up" purposes, not for a particular problem. Additionally, there is uncertainty in estimating the proportion of women who have been screened with mammography at some time in their lives as compared with the proportion who are routinely screened according to recommended age/frequency guidelines. Defining the reasons for mammography and documenting the prevalence of *regular* screening should be priority questions for prospective research on screening utilization.

The regression models reported here must be interpreted with caution. Stepwise forward selection of variables was used as a means of screening many bivariately associated variables to select those independently associated with screening behavior. Although this approach is suitable for screening it does not necessarily result in valid estimates of effect size.[15] The results of this analysis may be used to develop specific models which can then be explicitly estimated and tested in another data set.

Perception of barriers to mammography (exposure to radiation, pain, cost, and embarrassment) and to breast cancer screening have been suggested by theoretical models[16] and emphasized in previous studies.[17,18] Interestingly, none were significantly related to mammography behavior. Neither perception of severity, nor risk factor knowledge were associated. In contrast to the limited relationship of knowledge and belief factors, importance of having a regular physician, particularly a gynecologist and/or internist, is highlighted in this research.

Although the findings of this study cannot be generalized to minority or rural populations, they do highlight a particular challenge for public health to increase screening utilization behavior in older and lower-income women. Targets for education include their clinicians who need to initiate more effective discussion of screening requirements, motivation of public policy-makers to include coverage of screening mammograms to deal with any cost/access barrier, as well as education of women about the need to attend to breast health.

Editor Search Committee Seeks New Editor for American Journal of Public Health

An Editor Search Committee is actively recruiting a replacement for Dr. Alfred Yankauer who has announced his retirement as Editor of this *Journal*, effective July 1, 1990. The six-member search committee welcomes and solicits nominations and recommendations from the APHA membership and leadership to assist them in identifying the best available individual for this important salaried position. Nominations should be submitted as soon as possible, as the committee will meet several times to consider suggestions, applications, and support materials of potential candidates.

Names of potential candidates, along with letters of endorsement and other support materials, should be sent to: Editor Search Committee, American Public Health Association, 1015 15th St., NW, Washington, DC 20005.

The following criteria will be considered by the search committee in selecting the Journal editor:

- Comprehensive knowledge and broad perspective of the field of public health, with an appreciative understanding of its many disciplines and solid grounding in the basic sciences of epidemiology and statistics;
- Professional accomplishment and identity with the public health field, including respected standing among peers, combined with an extensive network of professional contacts who will provide expertise in soliciting and evaluating materials for publication;
- Demonstrated research skills, with evidence (such as credited publication in peer review journals) of firm grounding in a field of scientific inquiry within public health;
- Demonstrated writing, reviewing, and editing skills, enabling authoritative advice to authors on the suitability of prepared manuscripts, facilitating informed consideration of reviewer assessments, and equipping the preparation of appropriate editorials as needed;
- Freedom to devote substantial time to editor duties—as much as needed, presumably at least half time;
- Working knowledge of APHA and sympathy to its advocacy goals;
- Easy access to Washington, DC;
- An academic base is deemed highly desirable, preferably in a school of public health or a university health sciences center.

APHA is an affirmative action/equal opportunity employer.

Nulliparity, Decade of First Birth, and Breast Cancer in Connecticut Cohorts, 1855 to 1945: An Ecological Study

ROBERT A. HAHN, PHD, MPH, AND SURESH H. MOOLGAVKAR, MD, PHD

Abstract: Risk of breast cancer increases with age at first birth, and is lower in women who bear their first children while young than in nulliparous women. While previous studies have investigated risk of breast cancer in birth cohorts by examining partial aspects of cohort childbearing, the present ecological study assesses total cohort childbearing risk in Connecticut women born between 1855 and 1945. In each cohort, the proportion of women nulliparous and first bearing children in their twenties, thirties, and forties are weighted by relative risks associated with these events as ascertained in previous studies. Summed cohort childbearing risks are compared to the incidence of breast cancer in women 40 years of age and older in the same cohorts. Changes in decade of first birth and nulliparity do not explain the changes in breast cancer incidence observed: while cohort childbearing risk has declined over the period examined, breast cancer incidence has increased in the same cohorts. Alternative explanations for cohort increases in breast cancer incidence are reviewed. (*Am J Public Health* 1989; 79:1503–1507.)

Introduction

In the United States, Europe, and elsewhere, breast cancer incidence and mortality reached a low point in women born at the turn of the twentieth century and have been rising steadily in cohorts born thereafter.[1,2] The predominance of cohort effects in accounting for these secular changes in breast cancer incidence and mortality was noted early by MacMahon,[3] and has been well established by the modeling methods of indirect standardization.[1,2,4,5] MacMahon hypothesized that these cohortwise changes in incidence and mortality might correspond to changing patterns of childbearing.[3]

With several exceptions,[6–8] most case-control studies[9–13] have demonstrated that a woman's risk of breast cancer increases with the age at which she completes her first full term pregnancy. The risk of breast cancer in women first bearing a child before age 18 is estimated to be one-third that of women first bearing after age 34. Nulliparity is associated with greater risk of breast cancer than bearing a first child up to age 34, after which the risk associated with first births exceeds that of nulliparity.[13] A large retrospective cohort study[14] further supports these results.

Several studies[7,15–20] have examined the association of changing population childbearing patterns with changing patterns of breast cancer incidence and mortality. Using summary vital records from England and Wales, Connecticut, and the United States, MacMahon[15] examined the association of cohort fertility and breast cancer incidence and mortality; findings contradicted the hypothesis that fertility was inversely associated with breast cancer rates. In contrast, Armstrong[16] examined proportions of women in the US bearing first children by certain ages and live birth rates by certain ages in England and Wales; he found that childbearing trends accounted at least in part for the cohort variation in breast cancer incidence (in Connecticut) and mortality (in the US and in England and Wales). Likewise, Blot[17] found parallels between proportions of US women nulliparous between ages 20–24 and breast cancer mortality in the same cohorts. Wigle[18] also demonstrated associations between marital and fertility characteristics of Canadian women and their rates of breast cancer incidence and mortality. On the other hand, based on correlations among rates of breast cancer mortality among single and married women in nine nations and regions within them, Hems and Stuart[19] claimed that international differences in breast cancer mortality were associated with diet but not with fertility. Most recently, White[20] predicted that delayed childbearing in cohorts of women born since 1945 will yield breast cancer incidence significantly greater than that of preceding cohorts, in which early childbearing was more common.

Other than White's predictive analysis, these studies have shortcomings of two sorts. Some[7,15] have examined risk factors tangential to those now recognized to be associated with rates of breast cancer, for example, cohort fertility by older ages, and proportions married at 20–24 and at 40–44 years. Further, all of these studies examine one or several aspects of cohort childbearing events, e.g., nulliparity between ages 20 and 24, first birth by certain ages, but not the overall cohort history of childbearing. Investigation of isolated elements of cohort childbearing may mask other cohort childbearing risk factors for breast cancer which either support or oppose the particular cohort risk factor investigated. For example, while one cohort may have apparently greater risk than another cohort because of high nulliparity in ages 20–24, it may also have lower risk than the other cohort because of a high rate of first births to women younger than 20 years. Apparent associations and non-associations between partial cohort childbearing events and breast cancer outcomes may thus be misleading.

The present study used vital records and Connecticut Tumor Registry data to examine the association between total cohort childbearing history—nulliparity and decade of first birth—and breast cancer incidence in the population of Connecticut women born between 1855 and 1945.

Methods

Information on cohort childbearing events was abstracted from the Connecticut Vital Statistics Report (1879–1945),[21] Vital Statistics of the United States (1946–1982),[22] and the US Census of Population (1880–1980).[23] Information on breast cancer incidence in Connecticut women, ages 20 to 79 years, from 1935 to 1982 was provided by the Connecticut Tumor Registry,[24] as reported in Stevens, *et al*,[2] and updated.

This paper, submitted to the Journal October 4, 1988, was revised and accepted for publication May 9, 1989.

Cohort Decades of Firth Birth and Nulliparity

Because Connecticut Vital Statistics Reports present information on women bearing their first children in time intervals of varying length, but commonly in 10-year age categories, e.g., between ages 20 and 29, the present investigation is constrained to a comparison of decades of first birth. Numbers of women bearing first children in each year were aggregated into 10-year groupings centered on decade years (in which Census data were gathered), e.g., 1885–1894 (with decade mid-year 1890), 1895–1940 (mid-year 1900), etc. Since Connecticut Vital Statistics Reports were first published only in 1879, information on first births at different ages in the 1880 "mid-year" was aggregated from 1879 to 1884.

Proportions of women bearing first children in their second, third, fourth, and fifth decades were calculated by dividing numbers of first births in each age group by the population of that group. Since vital registry data on first births for the first Census period (1880) were available only for six of the 10 years in one interval (1879–1984), the proportions of 2nd to 5th decade first births for this period were estimated by dividing the numbers of births by 6/10 of the appropriate Census figures for each age group.

Resultant proportions were reorganized according to the year of birth of the mothers. Thus, proportions of women who bore a first child in their second decade (i.e., ages 10–19) between 1879 and 1884 were associated with those who first bore in their third decades (i.e., 20–29) between 1885 and 1894, and with those who first bore in their fourth decades (i.e., 30–39) between 1895 and 1904, and so on; all of these women were born between 1855 and 1874, a 20-year span referred to by its mid-year as the cohort of 1865.

While a few women were reported to bear first children after age 50, for the purposes of this analysis it was assumed that a women who had not borne a first child by age 50 was nulliparous. Cohort nulliparity was calculated by subtracting from *one* the sum of proportions of cohort women who had borne a first child in their second through fifth decades. That is,

$$\text{Cohort Nulliparity} = 1 - (FB_2 + FB_3 + FB_4 + FB_5),$$

where FB_n = proportion of cohort women bearing a first child in their n^{th} decade.

Cohort Childbearing Breast Cancer Risk

Cohort proportions of women nulliparous or first bearing children in different decades were weighted by the relative risks ascribed to these childbearing events by the multination case-control study of MacMahon, *et al*:[10]

Age/First Birth:	Nulliparous	<20	20–24	25–29	30–34	>34
Risk	1.0	.48	.59	.76	.91	1.10

In order to make the relative risks of five-year age groups from the multi-nation[10] study commensurate with the decades of first birth in the present study, a mean of relative risks within decades was taken to estimate the relative risk for each decade. Since women older than 40 contributed less than 0.5 percent of cohort first births, their contribution to childbearing risk was no longer considered. The total nulliparity and first birth decade risk of breast cancer in cohorts was then estimated by summing the relative risks specific to each childbearing category, weighted by the proportions of each childbearing category in the cohort. That is,

$$\text{Childbearing Breast Cancer Risk} = FB_2 \times RR_2 + FB_3 + FB_4 \times RR_4 + \text{Proportion Nulliparous} \times RR_{\text{Nulliparity}},$$

where, as above,

FB_n = the proportion of cohort women bearing a first child in their n^{th} decade,

and where,

RR_n = the risk of breast cancer given this event, relative to nulliparity.

Breast Cancer Incidence and Standardized Incidence Ratios

Since the first birth "exposures" considered were those occurring to cohort females by age 40, only breast cancer incidence after this age was analyzed as a possible outcome. Incidence data for women older than 40 years were grouped into 10-year age categories, and arrayed by cohort to parallel available information on childbearing exposures. The number of cases divided by the corresponding sum of woman-years at risk gave the incidence of breast cancer in this group during this period.

To compare cohort experience of breast cancer incidence and changes of breast cancer incidence between cohorts, we computed an aggregate incidence measure for the cohort. Since age-specific data are missing in the youngest cohorts, the usual methods of direct and indirect standardization do not apply. Following the method of Breslow and Day,[1] we computed an internally standardized incidence ratio for each cohort. The method assumes that age effects are constant in all cohorts, and cohort effects constant for each age; both parameters are estimated for all ages and all cohorts by assuming their constancy in cells for which no data are available. It is assumed that the populations are large, and that disease events are rare and well characterized by the Poisson distribution. Further, the expected number of events (incident cases of breast cancer) in age group i and birth cohort j is assumed to be $E_{ij} = N_{ij} \times a_i \times b_j$, where N_{ij} is the population (woman years) at risk in age group i and cohort j, a_i is the effect of age group i, and b_j is the effect of birth cohort j. The parameter, b_j, can be thought of as an internally standardized incidence ratio. Maximum likelihood procedures are then used to estimate the parameters of the model. This method yields a summary incidence ratio for cohort data derived from cross-sectional studies.

Results

Cohort Childbearing Breast Cancer Risk

For all cohorts of Connecticut females born between mid-years 1865 and 1935, the largest proportion of women have borne a first child in their third decade; the second largest proportion are nulliparous, except for women born in mid-year 1935; the smallest proportions have borne first children in their 2nd or 4th decade (Table 1). Together, cohort proportions of women either nulliparous or first bearing children in their third decades account for between 72 percent and 83 percent of cohort women. Predominant cohort trends are the large, though irregular, increase in the proportion of women bearing their first children in their twenties and the correspondingly large decline in nulliparity.

Weighting of cohort childbearing proportions by the corresponding relative risks yielded a cohort childbearing breast cancer risk profile (Figure 1) indicating: a general declining trend from earlier to later cohorts, interrupted by a small increase from the cohort of 1865 to that of 1875, and a larger increase from the cohort of mid-year 1895 to that of 1905. These risk estimates correspond mainly to changing proportions of third decade first births and nulliparity. Similar

TABLE 1—Proportions of Connecticut Women Nulliparous and First Childbearing in Different Decades (2nd–4th) by Birth Cohort Mid-Year, 1865–1935

Cohort Mid-Year of Birth	Nulliparas	Woman's Age at First Childbirth		
		10–19	20–29	30–39
1865	0.33	0.11	0.46	0.09
1875	0.36	0.10	0.44	0.09
1885	0.28	0.10	0.51	0.10
1895	0.26	0.12	0.53	0.08
1905	0.30	0.13	0.43	0.14
1915	0.21	0.09	0.55	0.15
1925	0.13	0.09	0.70	0.08
1935	0.10	0.14	0.70	0.06

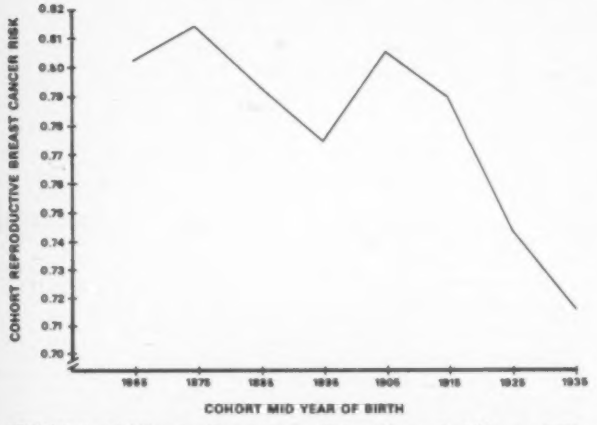

FIGURE 1—Childbearing Breast Cancer Risk in Connecticut Women, 1855–1945

breast cancer childbearing risk profiles (not shown here) derive from application of the relative risks from the large cohort study of Tulinius, *et al,*[14] and from the meta-analysis of White.[20]

Breast Cancer Incidence and Age-Adjusted Incidence Ratios

Incidence among women age 40 and older has increased steadily, with possible interruption in the cohort of 1885 for 70 year old women, of 1895 for 60 year old women, and of 1935 for 40 year old women (Figure 2). (The study of Stevens, *et al,*[2] indicated a trough in the standardized incidence ratio between Connecticut cohorts of 1885 and 1895 and a possible decline following the cohort of 1925.)

The standardized incidence ratio in women 40 years and older showed a general increase from the earliest to the last cohorts (Figure 3). Only from the cohort of 1905 to that of 1915 was there a slight decline in the incidence ratio, followed again by an increase—a more gradual increase than that preceding the decline. Points of inflection showed a rather different pattern from Figure 11 in Stevens, *et al,*[2] principally because Stevens' model incorporated year of event (that is, the interaction between age and cohort). In addition, whereas Stevens, *et al,* considered women 20 years and older in five-year age and cross-section categories, we considered only women 40 years and older in 10-year age categories and 10-year cross-sections. Our study also includes three years of more recent data.

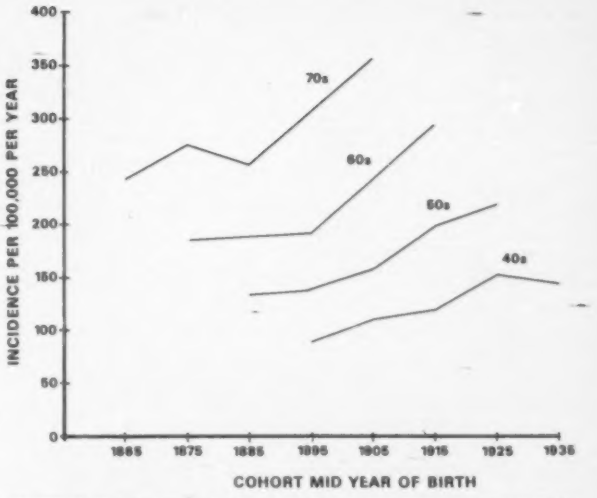

FIGURE 2—Breast Cancer Incidence in Connecticut Women Ages 40–79, by Mid-Cohort Year of Birth

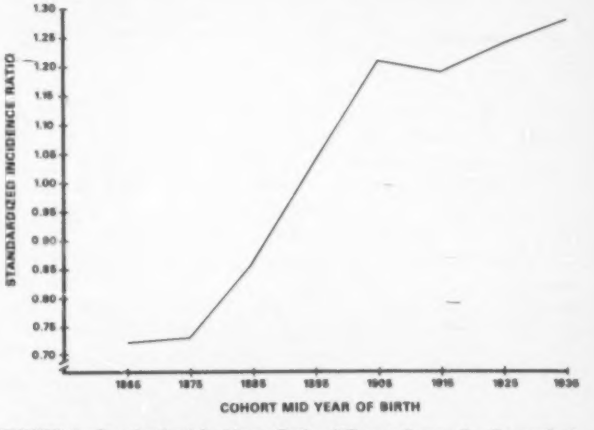

FIGURE 3—Standardized Incidence Ratio of Breast Cancer for Connecticut Women, 40 Years, by Mid-Year of Birth Cohort

Childbearing Breast Cancer Risk and the Standardized Incidence Ratio

Comparison of cohort childbearing breast cancer risk (Figure 1) and the standardized breast cancer incidence ratio for the same cohorts (Figure 3) indicated clearly opposing trends. While childbearing proportions of cohorts would have predicted a general fall in incidence, a generally increasing trend was observed in the standardized incidence ratio. Indeed, higher predicted childbearing breast cancer risk was associated with lower actual incidence ratios, and vice versa.

Comparison of childbearing breast cancer risk (Figure 1) with age-specific incidence rates (Figure 2) also showed a general opposition of trends.

To review the comparisons made in prior population based studies of this issue[7,15–20] with evidence from the present data, we compared the standardized incidence ratio with each of the childbearing proportions—nulliparity, 2nd, 3rd, and 4th decade first births. Discernible relations were contrary to those hypothesized. For example, the proportion of 4th decade first births was unrelated to the standardized

incidence ratio, and the proportion of nulliparas was inversely related.

Discussion

This ecological study examines the association of basic reproductive events—childbearing and decades of first birth—with subsequent risk of breast cancer for all Connecticut women born between 1855 and 1945. Predicted changes are contrary to those observed. While changing childbearing patterns predict a general decline of breast cancer incidence from the cohort of 1865 to that of 1935, the standardized breast cancer incidence ratio generally increases.

These findings are consistent with the large population-based cohort study of Tulinius, *et al*,[14] in which nulliparity and age at first birth were significantly associated with breast cancer incidence *within* cohorts, but predicted incidence changes *between* cohorts contrary to those observed. It may be noted that international differences in childbearing patterns, e.g., nulliparity and early first births, likewise cannot explain the large international differences in breast cancer incidence or mortality, for example, the 4- to 5-fold differences between the US and Japan.[25,26] In fact, breast cancer mortality among US males is also roughly four times that of Japanese males, suggesting that factors unrelated to gender and childbearing history are important in determining international differences.[27]

The conclusions of the present study do not contradict the association of nulliparity and age at first birth with breast cancer incidence. They suggest, however, that changes in breast cancer incidence among cohorts cannot be explained on the basis of changes in cohort childbearing. Cohortwise increases in breast cancer incidence, not only in Connecticut but elsewhere also,[2] have not been accounted for.

Several other recognized risk factors merit further consideration.

Age at Menarche and at Menopause: Early menarche and late menopause are recognized risk factors for breast cancer.[13] While age at menopause has remained relatively constant over the last century,[28] age at menarche has declined at a rate estimated at two months per decade,[29] thus suggesting an increase in breast cancer incidence.

Oophorectomy: Oophorectomy has been shown to be associated with subsequent decreased risk of breast cancer.[13] Armstrong[16] and others have attempted to show a negative association between rates of hysterectomy and breast cancer incidence. This comparison is misleading since it is not hysterectomy, but associated oophorectomy which affects breast cancer risk reduction. Changing rates of oophorectomy have not been examined for periods prior to 1960,[30] but this operation is probably rare and relatively recent, and thus is unlikely to be associated with the breast cancer changes considered here.

Oral Contraceptive Use: The effect of oral contraceptive use on subsequent breast cancer is a matter of controversy. Pike, *et al*,[31] have found that oral contraceptive use prior to first full term pregnancy increases the risk of breast cancer in young women (younger than 32 years). Vessey, *et al*,[32] and others[33] find no such effect. Despite their current prevalence, the recency of oral contraceptives precludes their association with the secular changes considered here.

First Trimester Abortion: The association of abortions prior to first full term pregnancy with increased risk of breast cancer in young women is also a matter of controversy[32,33] Documentation of abortion prior to the 1973 Supreme Court decision is problematic, but this procedure has probably become widespread only recently, and thus again is unlikely to be associated with the changes considered here.

Multiparity: While multiparity and age at birth beyond the first have been found to have less effect on breast cancer than age at first birth,[10,13] studies of high parity populations indicate a strong effect.[14,34,35] In the US, rates of parity of two or more have generally increased since 1900,[36] suggesting a decline in breast cancer rates.

Lactation: While the international studies of MacMahon, *et al*,[37] had shown that, after controlling for parity, the effects of lactation in reducing breast cancer risk disappeared, recent studies again indicate an association, but principally in premenopausal women.[38,39] It is not clear how long-term secular changes in lactation could be assessed.[40]

Diet and Body Weight: Diet and one of its correlates, body weight, have been associated with international differences and secular changes in breast cancer rates.[7,41] Historical records of national and per capita consumption of different food products may allow exploration of the association of nutritional changes and changes in breast cancer incidence.

Electricity and Uninterrupted Light: There is experimental evidence in the rat that exposure to electro-magnetic fields or light reduces pineal production of melatonin; in turn; decreased production of melatonin leads to increased ovarian estrogen and pituitary prolactin production. Stevens[42] has hypothesized that increased exposure to light and electromagnetic fields may increase the risk of breast cancer in humans. Thus, it is interesting to speculate that increasing electrification may be responsible for some part of the observed secular trend. However, it is highly unlikely that the effect of electrification would be seen as changes in risk by cohort.

Secular trends and international differences in this common disease remain largely unexplained. The present study provides further evidence that prominent childbearing events in cohorts predict changes in cohort breast cancer contrary to those which have occurred. Other risk factors must counteract these cohort childbearing trends. Efforts should be made to identify modifiable risk factors which might explain cohort increases in breast cancer incidence.

NH Law Center Announces Plan to Publish Interdisciplinary Journal

Franklin Pierce Law Center is launching a new interdisciplinary quarterly journal, *Risk: Issues in Health & Safety*. Manuscripts dealing with *basic* problems in health and safety management are being sought for future issues. Of particular interest are research reports or essays addressing strategies for reducing net risk or focusing on the normative issues involved in determining the acceptability of risk—particularly ones spanning traditional categories of occupational, environmental, medical, and consumer injury.

Comments, book reviews, announcements concerning events of interest to a broad interdisciplinary audience, and letters are also welcome.

Those who wish to receive a complimentary copy of the first issue, to be published in late fall or early winter of 1989, may write to Carol Ruh, Franklin Pierce Law Center, 2 White Street, Concord, NH 03301. Annual institutional subscriptions are $50; individual subscriptions, $25.

Thomas G. Field, Jr., JD, Professor of Law and founding member of the faculty of Franklin Pierce Law Center, will serve as editor of the new journal. Those interested in submitting a manuscript may send them to him at the Law Center address, or telephone (603) 228-1541 for further information. FAX Telecopier: (603) 224-3342. The Law Center also publishes *Idea: The Journal of Law and Technology*.

Late-Stage Diagnosis of Breast Cancer in Women of Lower Socioeconomic Status: Public Health Implications

THOMAS A. FARLEY, MD, AND JOHN T. FLANNERY, BS

Abstract: To assess the success of breast cancer control activities in Connecticut, we examined data from the Connecticut Tumor Registry, determining differences in breast cancer stage at time of diagnosis over time and in selected subgroups. From 1982 to 1985, the percentage of women with cancer confined to the breast increased from 54.0 percent to 61.3 percent. During 1984 and 1985, lower socioeconomic status (SES) women with breast cancer were less likely than higher SES women to be diagnosed with early-stage disease (56.9 percent vs 62.7 percent). SES was estimated by census tract of residence. In the same years, the overall incidence of breast cancer was greater in higher SES women. Projections based on these incidence data found that lower SES women, as compared to higher SES women, had a higher rate of expected breast cancer deaths (24.6 vs 19.7 per 100,000), and a greater percentage of those deaths considered preventable by early detection (22 percent vs 11 percent). The rate of preventable deaths in lower SES women was 2.5 times as great as that for higher SES women (5.3 vs 2.1 per 100,000). Tumor registries can serve as useful surveillance systems to aid cancer control programs. Breast cancer early-detection programs should give special attention to lower SES women. (*Am J Public Health* 1989; 79:1508–1512.)

Introduction

The long-term survival of women with breast cancer is dependent on the stage of disease at the time of diagnosis.[1] Attempts to control breast cancer deaths have therefore relied on promoting early cancer detection and treatment. Prospective studies have demonstrated the success of screening programs in both detecting cancers in early stages and decreasing breast cancer mortality.[2–5] However, these studies have been in groups of women enrolled in health maintenance organizations or recruited for special projects. In Connecticut, women have primarily been encouraged to have breast cancer screening by their individual physicians and through educational programs of the American Cancer Society. The extent to which these efforts have been successful in the general population of the state is unclear.

The success of the breast cancer control programs should be measurable initially as an improvement in the percentage of all breast cancers diagnosed at an early stage and ultimately as a decrease in the incidence of late-stage disease. Tumor registries regularly contain information on cancer stage, and can consequently serve as surveillance systems to guide cancer control activities. We examined recent trends in breast cancer stage at the time of diagnosis in the Connecticut Tumor Registry. We then evaluated cancer stage in selected subgroups of the population, and projected estimates of the number of deaths preventable by earlier detection in women of various socioeconomic groups.

Methods

The Connecticut Tumor Registry has collected information on all Connecticut cases of invasive breast cancer and carcinoma-in-situ in a consistent manner since 1941.[6] The cancer stage is determined for each case by trained Medical Record Technicians at the Connecticut Department of Health Services (DHS) from detailed clinical, surgical, and histological reports. The staging system for breast cancer, unchanged since the registry began, can be summarized as follows: 1) *carcinoma-in-situ*; 2) *local*—invasive cancer localized to the breast; 3) *regional*—cancer in the breast with spread to regional lymph nodes or pectoral muscles; 4) *remote*—presence of distant metastases. The tumor registry has contained basic demographic information since its inception, but data on census tract of residence, which allow an estimation of socioeconomic status, have been included only since 1984.

The outcome measured was the distribution of cancer stage at the time of diagnosis. Comparisons of stage distribution were made by year from 1975 to 1985; for 1984 and 1985 comparisons were also made by race, place of residence, and socioeconomic status (SES), as estimated from census tract information. Census tract coding was not possible for 778 (17 percent) of 4,524 women with cancer diagnosed during those years. Data from these women were analyzed separately to test for potential bias the incomplete coding may have caused. We analyzed three different markers to identify census tract socioeconomic level (as determined in the 1980 census): 1) median household income; 2) percentage of persons below the poverty line; and 3) percentage of adults who have completed a high school education. These three variables were closely correlated, and the various definitions of census tract socioeconomic level led to identical conclusions; the data presented use the percentage of census tract adults who were high school graduates as the sole SES marker. Women were grouped into quartiles. The lowest SES quartile contained census tracts with 15–61 percent of adults who were high school graduates. The middle two quartiles were combined to form the middle SES group, which contained census tracts with 62–82 percent of adult high school graduates. The highest quartile contained census tracts with 83–97 percent of adult high school graduates. For analysis of Black women stratified by SES, the middle and higher SES groups were combined because of the small number of cancers in each stratum.

Population denominators for calculations of incidence trends from 1975 to 1985 were linear estimations based on 1970 and 1980 census figures for each age group. Incidence rates by SES were calculated using census tract population data from the 1980 census. Age-adjustment was done by the direct method, using the 1980 Connecticut population as the standard.

Address reprint requests to Thomas A. Farley, MD, Louisiana Department of Health and Hospitals, Epidemiology Section, 325 Loyola Ave., Room 615, P.O. Box 60630, New Orleans, LA 70160. Dr. Farley is assigned there from the Division of Field Services, Epidemiology Program Office, CDC, Atlanta. Mr. Flannery is with the Connecticut Tumor Registry, CDHS, Hartford. This paper, submitted to the Journal December 22, 1988, was revised and accepted for publication May 2, 1989.

The projected number of breast cancer-caused deaths in a cohort of women with breast cancer was derived according to the following general principle:

> Breast cancer-caused deaths = (Expected survivors in breast cancer cohort from actuarial estimates) − (Expected survivors in breast cancer cohort given presence of breast cancer)

The terms of this equation were calculated using: 1) 5-year survival rates by age and race from 1983 life tables; 2) 5-year relative survival rates for each stage established nationally[1] and in Connecticut; 3) estimates of the effect of SES on stage-specific 5-year relative survival rates from published studies;[7–9] and 4) mean annual numbers of breast cancer cases by age, race, and SES group during 1984–85 (see Appendix). "Nonpreventable" deaths represent similar estimates, assuming that the stage distribution in each age group achieved a goal as follows: *carcinoma-in-situ*—10 percent, *local*—60 percent, *regional*—25 percent, *remote*—5 percent of the total. This goal was felt to be reasonable based on published studies of breast cancer screening[5,10] and the current trend in Connecticut. "Preventable" deaths were defined as the difference between projected deaths and "nonpreventable" deaths. To help interpret these numbers of deaths, we calculated projected death rates by dividing them by the number of women in the population from which the cancer cases arose; population denominators were taken from the 1980 census. To study the longer-term impact of early detection, we projected 10-year death rates with similar methods.

We then assessed the reliability of these deaths rate estimates by varying the assumptions used, including: changing the program "goals", using different estimates of relative survival rates, and eliminating the differences in stage-adjusted survival by SES group. Changing these assumptions altered the magnitude of the projected death estimates, but caused only very small relative differences, and produced no difference in the conclusions regarding the SES group at highest risk. In general, increases in 5-year survival rates led to increases in the expected beneficial effect of early tumor detection, and increases in the ratio of projected preventable deaths in higher versus lower SES women. The data presented use 5-year survival rates established nationally (which include data from Connecticut)[1] and 10-year survival rates from the 1975–77 Connecticut breast cancer cohort.

The statistical significance of trends in disease stage was evaluated using extensions of the Mantel-Haenszel chi-square test for trends with multiple levels of exposure and multiple levels of disease.[11]

Results

Between 1975 and 1985, 21,131 breast cancers were diagnosed in Connecticut women. For 20,165 (95.4 percent) cancers, the available information was sufficient to accurately determine stage. In individual years, cancers of unknown stage represented between 3.9 percent and 6.0 percent of all cancers, with no increasing or decreasing trend. The trend of cancer stage among those cases in which information was complete is presented in Table 1. Between 1975 and 1981, there was little variation from year to year in stage at diagnosis, with no overall trend ($p = 0.29$). During this time, the percentage of cancers of known stage that were confined to the breast (*carcinoma-in-situ* and *local* stages) ranged from 52.2 percent to 55.9 percent. However, from 1982 to 1985 this percentage increased from 54.0 percent to 61.3 percent ($p = 0.0001$). Over these four years, the age-adjusted incidence of cancer in later stages (*regional* and *remote*) decreased slightly, from 5.06 to 5.02 cases per 10,000, while the breast cancer incidence overall increased from 11.6 to 13.6 and the incidence of disease confined to the breast increased from 5.9 to 8.0 cases per 10,000 (Figure 1).

During 1984 and 1985, the years in which information on SES was available, cancer stage was more closely and consistently related to SES than area of residence. There were no differences in the distribution of cancer stage among women residing in different counties. However, in cities of greater than 100,000 population (which have a disproportionately large share of lower SES women) only 56.7 percent of women presented with tumors confined to the breast, compared to 61.0 percent of women in smaller cities and towns ($p < 0.001$). Table 2 shows that women in the lower SES group, compared to women in the higher SES group, were less likely to have *carcinoma-in-situ* (6.2 percent vs 8.5 percent) or cancer confined to the breast (56.9 percent vs. 62.7 percent), and more likely to present with *remote* disease (8.9 percent vs 5.9 percent; $p = 0.001$ for trend). Middle SES group women had intermediate values. Black women, compared to White women, were less likely to have *carcinoma-in-situ* or cancer confined to the breast and more likely to have *remote* disease ($p = 0.007$ for trend). The differences in cancer stage by SES group were still present when cases were stratified by race ($p = 0.03$ for White women, $p = 0.04$ for Black women). There were no important differences between

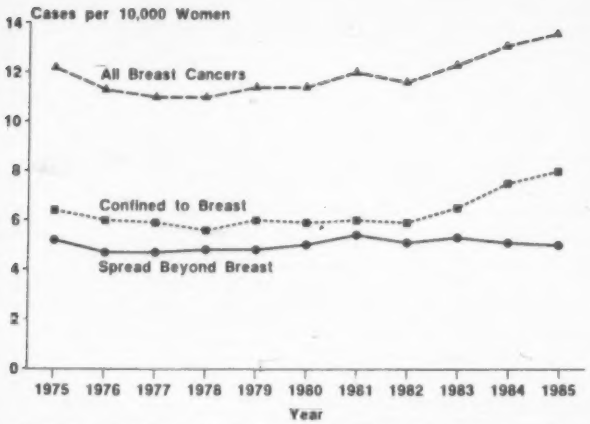

FIGURE 1—Incidence of Breast Cancer by Stage at Diagnosis, Connecticut, 1975–85

any of these subgroups in the percentage of cancers for which the stage was unknown.

The 778 women without census tract information were similar to women in known census tracts in the percentage that were Black or urban residents. Among the 684 of these women for whom the stage was known, the distribution of cancer stage was similar to that of women in known census tracts.

Population-based rates of the different cancer stages were calculated for each SES group. Lower SES women had lower crude and age-adjusted rates of breast cancer overall and of early-stage disease, but a slightly higher rate of metastatic disease (Table 3).

The numbers of cancer cases in each stage were then used to calculate projected breast cancer death rates for the different SES groups (Figure 2). These rates indicate the proportion of women annually diagnosed with fatal breast cancer ("fatal" meaning expected to die from breast cancer within five years from the time of diagnosis). To estimate the expected benefit of a moderately successful early detection program, these death rates were then separated into "preventable" and "nonpreventable" death rates as described. There were small differences among SES groups in the rates of "nonpreventable" deaths. However, lower SES women, compared to higher SES women, had a 25 percent higher projected breast cancer death rate (24.6 vs 19.7 per 100,000) and a greater percentage of those deaths classified as "preventable" (22 percent vs 11 percent). The preventable breast cancer death rate for lower SES women was 2.5 times as great as that for higher SES women (5.3 vs 2.1 per 100,000). A similar analysis projecting 10 years from the time of diagnosis produced parallel results; lower SES women had a 34 percent higher projected death rate (32.0 vs 23.8 per 100,000), and a greater percentage of those deaths "preventable" (20 percent vs 9 percent).

Discussion

The Connecticut Tumor Registry has for many years been an invaluable source of data on cancer incidence trends.[6] Recent advances in our understanding of cancer prevention allow us increasingly to use tumor registries like this as surveillance systems to aid in the design and evaluation of cancer control activities. As surveillance systems, tumor registries not only provide accessible information about the overall success or failure of control activities over time, but also identify subgroups of the population at unusually high risk of fatal disease.

Our analysis of the tumor registry data shows a shift toward early breast cancer detection in Connecticut in the 1980s, as indicated by an increase in the percentage of tumors diagnosed in early stages and a slight decrease in the incidence of later-stage disease. This shift represents an acceleration of the more gradual long-term trend toward earlier diagnosis of breast cancer present since the 1940s.[12,13] It is probable that this long-term trend is responsible (together with an improvement in stage-specific survival rates) for the stabilization of breast cancer mortality rates, in spite of a real increase in breast cancer incidence.[12–14]

No data are available regarding the frequency of screening mammograms or breast examinations in Connecticut. If breast cancer screening is responsible for the shift toward early-stage diagnosis, then we would hope to soon see a further decrease in the population-based incidence of *regional* and *remote* stage disease. Statewide surveillance of breast cancer should therefore periodically assess the incidence of disease by stage to monitor the success of early detection programs.

Both White and Black women in lower SES census tracts were more likely than race-matched women in higher SES census tracts to have later-stage disease at the time of breast cancer diagnosis. A definition of SES based on census tract information subjects the analysis to potential bias caused by an "ecologic fallacy." However, we would expect that the misclassification of women by this group attribute would tend to bias the data toward finding no differences by SES. In addition, our data show a consistent trend over three SES groups, are similar to the analysis of stage by race, and are similar to the findings of stage versus SES found by other authors.[7,8,15,16]

The relation between lower SES and late-stage diagnosis found by others has been noted in the process of correcting for the effect of stage on long-term survival rates. Rather than correcting for tumor stage, we used it as the outcome to measure the success of control activities. This allowed us to assess the effect of early detection programs independent of the effects of primary prevention and treatment programs.

Breast cancer screening programs may detect some early tumors which do not have the potential to progress to clinical cancer. Classifying these tumors as breast cancer would artificially increase both breast cancer incidence and the percentage of tumors diagnosed in early stages. This phenomenon may be partly responsible for the temporal trend and socioeconomic differences in early cancer rates. However, such benign tumors would not alter the population-based incidence of *regional* or *remote* cancer and would not have a significant impact on our projected breast cancer mortality rates.

Although lower SES women are more likely to present with later stage-disease and have poorer stage-adjusted 5-year survival rates[7,9] than higher SES women, they have a lower overall incidence of breast cancer than higher SES women. Therefore it is not immediately apparent which group should be a target of control programs. However, we estimate that these SES differences will lead to a 25 percent increase in deaths for lower SES women compared to higher SES women, with these deaths more than twice as likely to be preventable by early tumor detection.

We have had to make several assumptions in calculating these projected death rates. In particular, we have assumed

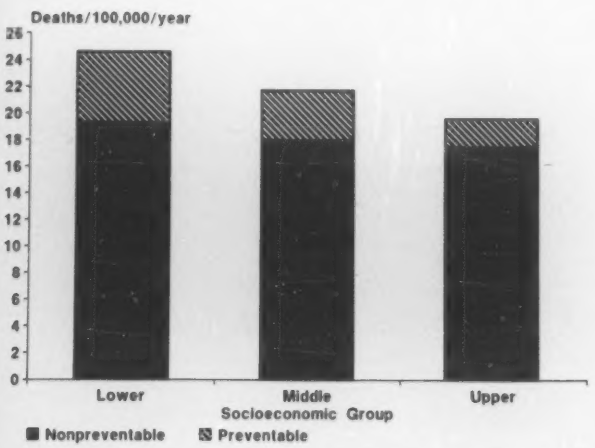

FIGURE 2—Projected Breast Cancer Death Rates for Cases Diagnosed in Connecticut during 1984–85

that within each SES group, long-term stage-specific cancer survival rates would remain unchanged after an early-detection program. This assumption is related to the effect of lead-time on cancer survival and mortality. A theoretical problem exists in assessing the benefit of screening programs if women who have cancers detected early do not have the expected improvements in long-term survival—if these women's deaths are neither prevented nor postponed, but simply occur further from diagnosis. However, over time, as cancers in Connecticut have been detected earlier, long-term survival rates for early-stage disease have actually increased (10-year rates are presently 99 percent for carcinoma-in-situ, 83 percent for cancer localized to the breast). Furthermore, two studies have demonstrated that screening has a beneficial long-term effect on mortality independent of its effect on diagnostic lead-time.[2,3,5] Therefore it is likely that the assumption of constant stage-specific survival rates is sufficiently valid to provide useful estimates regarding the benefit of early detection programs.

While the magnitude of our death rate projections depends on the numerical assumptions we have made regarding disease stage and survival, the trend toward a substantial increase in preventable deaths in lower SES women was present regardless of such assumptions. We believe these projections, combined with the established benefit of early tumor detection in decreasing cancer mortality,[2–5] provide strong justification for prevention programs to direct special attention to lower SES women.

It is probable that women of lower SES present with later-stage disease because of a combination of decreased access to medical care and a decreased awareness of or belief in the importance of early cancer detection. In the National Health Interview Survey, Black women had lower rates of utilization of breast examinations or mammography than White women, and among those >40 years old, were twice as likely as White women to have never heard of mammography.[17] Our data suggest that this difference may be due more to socioeconomic status than race. Data from neighboring Rhode Island indicate that among all women who had not had a mammogram in the past year, the most important reason for not having had the test was that they had believed it was unnecessary.[18] It is important to better define the precise reasons why women in lower SES groups appear less likely to use breast cancer screening techniques.

Connecticut has recently passed a law ensuring that all private and public medical insurance plans—including Medicare—pay for the cost of screening mammography. The Connecticut Department of Health Services is currently working with the American Cancer Society in the state to find ways

of better reaching lower SES women. We hope these efforts will improve early cancer detection and thereby contribute to the prevention of breast cancer morbidity and mortality.

APPENDIX

Estimated 5-Year Survival Rates by Cancer Stage

For each SES group, the number of projected breast cancer deaths (D) was calculated as the sum for each race of the following:

$$D = \sum_{s}\sum_{a} L_a \times C_{a,s} - \sum_{s} P_s \sum_{a} L_a \times C_{a,s}$$
$$= \sum_{s} (1 - P_s) \times (\sum_{a} L_a \times C_{a,s})$$

where s = stage, a = age-group, L_a = estimated 5-year actuarial survival for each age-group, P_s = estimated 5-year relative survival for each stage in that SES group (see below), and $C_{a,s}$ = number of actual cases of breast cancer in each age-group and stage. "Nonpreventable" deaths were calculated using the same equation except that the number of actual cases was replaced by the goal number of breast cancer cases in each stage.

	5-year Relative Survival by Cancer Stage				
SES Group	In situ	Local	Regional	Remote	All stages
High	.993	.912	.748	.190	.811
Middle	.989	.899	.685	.174	.782
Low	.986	.886	.622	.158	.754

The estimated 5-year relative survival rates were generated by adjustment of data from the Surveillance, Epidemiology, and End Results (SEER) program[1] with estimates of previously noted effects of SES on survival rates.[7–9] The rates used were as follows:

Manual Being Developed to Assist Local Boards of Health in Policy-Making

To help improve the capabilities of local boards of health, a manual is being designed by the Association of North Carolina Boards of Health (ANCBH), under a $5,000.00 grant from the W. K. Kellogg Foundation. That financial support will enable ANCBH to review available information on public health policy-making and develop new resources specifically for boards of health in North Carolina, according to Vaughn Upshaw, Administrative Director of ANCBH in Pittsboro, NC. However, he added that the manual would be available to *all* boards of health in the US.

The manual is expected to offer a review of the state statutes in North Carolina, and also provide guidelines for board members to improve their assessment of community needs, policy-making skills, knowledge of agency operations, and advocacy for public health.

Local boards of health are empowered by the state to protect and promote public health. According to ANCBH President Ronald Tucker, "Growing concern for our environment and personal health increases the need for informed local officials." Few resources are available locally to boards of health on how to act effectively, he added. "Board members, health directors, health department staff, and the public will benefit from more knowledgeable and effective boards of health."

For further information, contact Vaughn Upshaw, MPH, ANCBH, PO Box 1009, Pittsboro, NC 27312. Tel: 919/542-4244.

Sentinel Health Event Surveillance: Skin Cancer of the Scrotum in New York State

AURA L. WEINSTEIN, MPH, HOLLY L. HOWE, PHD, AND WILLIAM S. BURNETT, MD, DRPH

Abstract: Skin cancer of the scrotum is a disease that has been identified as a sentinel health event (occupational) (SHE(O)) that is necessarily occupationally related. The present paper examines the feasibility of using this disease in active cancer surveillance in New York State. After consulting cancer case reports, hospital records, death certificates, and city directories, we obtained occupational data for 17 of 22 cases of nonmelanoma skin cancer of the scrotum diagnosed between 1979 and 1984. Only three cases had occupations previously linked to scrotal cancer, while 11 of 19 cases had one or more possibly contributory medical conditions. The probable underreporting of scrotal cancer cases and incompleteness of occupational data may limit the usefulness of scrotal cancer as a sentinel health event (occupational) unless additional steps are taken. (*Am J Public Health* 1989; 79:1513–1515.)

Introduction

Cancer of the scrotum, which has been associated with exposures to numerous hydrocarbon products,[1] has been identified as a sentinel health event (occupational) (SHE(O)).[2] A SHE(O) is defined as:

> an unnecessary disease, disability, or untimely death which is occupationally related and whose occurrence may: 1) provide the impetus for epidemiologic or industrial hygiene studies, or 2) serve as a warning signal that materials substitution, engineering control, personal protection, or medical care may be required.[2]

SHE(O)s can be broken down into two broad categories: those which are necessarily occupationally related and would be unlikely to occur in the absence of occupational exposures, and those which may or may not be occupationally related. In the original SHE(O) paper,[2] scrotal cancer was identified as one of the three malignant neoplasm SHE(O)s that are necessarily occupationally related.

The Cancer Surveillance Program of the New York State Department of Health is assessing the feasibility of active surveillance using data from the State Cancer Registry to monitor SHE(O) cancers. This feasibility study has examined in detail the occurrence of necessarily occupationally related SHE(O) cancers in New York State and the information on individuals with these cancers obtainable from routine data sources. This paper presents the results of this examination for skin cancer of the scrotum.

Methods

The source of data was the New York State Cancer Registry, which receives reports from physicians, laboratories, and hospitals on all cases of cancer diagnosed in the state, as required by law. Cases are also obtained from death certificates, and through reciprocal interstate reporting agreements. Based on various quality control studies, cancer reporting to the Registry is estimated to be over 95 percent complete for the state.[3] At the time the Registry case listing for this analysis was obtained, case reporting was complete through 1984.

Since it is the epithelial cancers of the scrotum that have been identified with occupational exposures, analysis was confined to these morphologic types. Reporting to the Cancer Registry of nonmelanoma skin cancers of the scrotum, which account for the majority of epithelial scrotal cancers, began in 1979. The present analysis includes cases reported from 1979 through 1984.

Cancer Registry data were supplemented by an examination of hospital records for the cases of nonmelanoma skin cancer of the scrotum identified through the Registry. Hospital records were reviewed for information on smoking history, occupational exposures, course of illness, and any prior or concurrent medical conditions that may have been related to the development of scrotal cancer. Information on occupation was also sought from city directories and from death certificates when appropriate.

Incidence rates for scrotal cancer were computed as average annual rates for the period 1979 through 1984. Rates were age-adjusted to the 1960 United States population to allow for the comparison of rates in different populations.

Results

The New York State Cancer Registry identified 30 incident cases of epithelial skin cancer of the scrotum in New York State residents between 1979 and 1984. This corresponds to an average annual age-adjusted incidence of 0.56 per million males. The epithelial cancers included 22 cases of nonmelanoma skin cancer, all of which were the squamous cell type, and eight other epithelial types such as adenocarcinoma and unspecified carcinoma.

Occupational History

The cancer case report requests information on employer, industry and usual occupation, but only eight of 22 nonmelanoma skin cancer cases had an occupation listed on the case report. These occupations tended to be in the managerial and professional, or service categories. Hospital records, obtained for 19 of the 22, confirmed any occupations listed on the cancer case reports and provided occupations for five additional cases—all in the skilled, semi-skilled, or unskilled labor category. Death certificates supplied occupational information for three more cases, and a city directory provided occupation information for another case. After consulting these sources, five occupations remained unknown. These results are summarized in Table 1.

TABLE 1—Occupational Categories of Males Diagnosed with Nonmelanoma Skin Cancer of the Scrotum, New York State, 1979–84, by Source of Occupational Information

Occupational Category[1]	Cancer Case Report	Hospital Records	Death Certificate	City Directory	Total
Managerial or professional	4	0	0	1	5
Skilled, semi-skilled or unskilled workers[2]	1	5	1	0	7
Service occupations	2	0	0	0	2
Technical, sales and support	1	0	1	0	2
Farm occupations	0	0	1	0	1
Total	8	5	3	1	17

NOTES: 1. Occupational categories derived from summary groupings found in the *1980 Census of Population: Alphabetical Index of Industries and Occupations*, US Department of Commerce, 1982.

2. Includes US Census categories Precision Production, Craft and Repair Occupations, and Operators, Fabricators and Laborers.

Five additional occupations remained unknown.

Three of the persons classified as skilled, semi-skilled, or unskilled workers had occupations that could have put them at elevated risk of scrotal cancer. These included a bridge painter who had reported occupational exposures to graphite and kerosene, a machinist who may have been exposed to carcinogenic cutting oils, and a mechanic for a heating equipment business who had possible exposure to soots and tars. Each of these substances has been linked with scrotal cancer.[1,4] None of the other occupations presented any apparent opportunities for relevant exposures to occur.

Medical Risk Factors

Medical records showed that eight of the 19 squamous cell skin cancer cases with available medical records had a prior history of cancer. Five of these prior cancers were skin cancers (two squamous cell, one malignant melanoma, one unspecified skin, and one mycosis fungoides). One other person had a history of psoriasis, which was treated with coal tar. The patient with mycosis fungoides had undergone PUVA (psoralen-ultraviolet-light) treatments, a regimen often used to treat psoriasis and linked to squamous cell cancers.[5] Other conditions which may have had significance in the development of scrotal cancer are a prior injury to the urinary tract, undescended testis, and "very poor hygiene." The latter condition has been identified as a risk factor for scrotal cancer from the days of Percivall Pott,[6,7] up to a recent case series.[8] There were 11 persons in all who may have had one or more possibly contributory medical conditions.

Other Geographic Areas

The age-adjusted rate (0.56 epithelial cases per million man-years) in New York State for 1979–84 compares with age-adjusted rates of 1.32 per million for Connecticut during the 45-year period 1935–79, and 0.97 per million in Connecticut for 1975–79.[5] More recent data from Connecticut* show an age-adjusted rate of 1.28 per million males for all cancers of the scrotum for the period 1978–84. If epithelial cancers still account for 75 percent of all scrotal cancers reported in Connecticut, then the epithelial scrotal cancer rate is roughly 0.95 per million males, nearly twice that observed in New York.

The age-adjusted incidence rate of 0.52 per million males observed for New York City was compared with that for Metropolitan Detroit, a northern industrial urban area with a similar proportion of black males. The Detroit figures for 1979–84** give an average annual age-adjusted rate of 1.14 cases per million males, which is again about twice that for New York City.

In New York, none of the 30 epithelial cancers of the scrotum reported through 1984 was the (less serious) basal cell carcinoma. Nine of 71 confirmed epithelial cancers in Connecticut from 1935 through 1979 were basal cell, and three of 16 epithelial cancers in Metropolitan Detroit from 1979 through 1986 were basal.

Discussion

Incidence rates of epithelial cancers of the scrotum in New York State and New York City are approximately half those of the Connecticut and Detroit SEER‡ areas, respectively. This may indicate some degree of underreporting, but the extent to which this deficit may also reflect true differences in occupational exposures is not known. The predominance of the squamous cell type also supports the possibility of differential underreporting of the less serious cases.

Skin cancer of the scrotum has been characterized as a cancer whose occurrence is unlikely in the absence of occupational exposures.[2] In the present study, evidence of a possible occupational origin was found for only three of the 17 cases for whom occupational data were available. In contrast, 11 of the 19 persons for whom hospital records were available had prior or co-existing medical conditions that might be related to their scrotal cancers.

One possible interpretation of these findings is that occupational cancer of the scrotum in New York State is at such a low level that "background" or nonoccupational cases predominate. However, the possibility of significant underreporting, particularly of uncomplicated cases, makes it conceivable that an occupationally related spatial or temporal clustering may not be reflected in Registry data.

A related issue is that of the completeness and quality of the occupational data that are available. Less than half of cancer case reports had occupation listed, and those occupations that were listed tended to be of the type where unusual exposures generally do not occur. For the remainder of cases, it was necessary to consult several sources of varying accessibility and completeness. Hospital records provided occupational information for more patients than the cancer case reports, but had to be sent for specially, a process often taking several weeks. New York State death certificates are generally good sources of occupational information, but their usefulness is limited for nonfatal diseases such as skin cancer of the scrotum. It was also not feasible to obtain death certificates for New York City residents, who made up 40 percent of the cases. City directories can provide occupational information, but are not a consistent source since complete listings are not available for all areas. After con-

‡SEER: Surveillance, Epidemiology, and End Results, the population-based cancer surveillance system established by the National Cancer Institute in 1970.

sulting all these sources, nearly one fourth of the occupations were still unknown. Furthermore, the occupations that were ascertained represent the usual or the most recent occupation; other pertinent occupations may not be recorded.

Steps may be taken to improve the representativeness and completeness of data on scrotal cancer cases and their occupations collected in the future. One would be to remind all physicians of their duty to report nonmelanoma skin cancers of specified sites, and of the proper format and reportable items. A second step might be to send a reminder to all hospital tumor registrars regarding the importance of completing the occupation section on the cancer case report. Obtaining more complete occupational histories would require contacting cases or their next-of-kin directly, often requiring more extensive resources than generally available for surveillance activities.

The Homeless Families Program—A National RWJ/HUD Initiative

A multi-million dollar public/private program for homeless families has been announced as a cooperative national initiative of the Robert Wood Johnson Foundation and the US Department of Housing and Urban Development (HUD).

The Homeless Families Program is intended to help communities develop the infrastructure necessary to strengthen the potential of homeless parents and their children to function successfully. The Johnson Foundation will make as many as eight two-year grants of up to $300,000 each to eligible cities (population 250,000 or more) or the counties in which these cities are located; Public Housing Authorities (PHAs) in jurisdictions selected under the competition will also be eligible for a share of the Section 8 certificates HUD will set aside for this purpose. The grants and housing certificates will support community-wide projects aimed at providing comprehensive health and supportive services and housing assistance to homeless families suffering from complex, often chronic, problems, including health and mental health problems, inadequate education or job training, and lack of day care and other services.

The goal of the Homeless Families Program is to show that even in the most dysfunctional families, appropriately designed health and support services, combined with suitable housing, can help parents become healthy and hopeful, and avoid becoming permanent members of the nation's underclass. The program also seeks to promote the long-term expansion of permanent housing options for these families.

Interested applicants should send a letter of interest to: **Dr. James O'Connell, Director, Homeless Families Program, Massachusetts General Hospital, 32 Fruit Street, Boston, MA 02114.** Limit the letter to two typed, double-spaced pages. Identify the parties to be involved in developing the application, documenting local government support, and generally outlining the project to be proposed. A contact person should be identified to serve as principal liaison during the application process. Application materials will be sent upon receipt of the letter. **The deadline for receipt of applications is December 22, 1989.** Grant recipients will be announced May 1990. The Robert Wood Johnson Foundation is at College Road, PO Box 2316, Princeton, NJ 08543-2316.

Carcinogenicity of Dark Liquor

KENNETH J. ROTHMAN, DRPH, CRISTINA I. CANN, AND MARVIN P. FRIED, MD

Abstract: To investigate whether the non-alcohol content of distilled alcoholic beverages affects the carcinogenicity of the beverage, we conducted an epidemiologic study of laryngeal and hypopharyngeal cancer. We interviewed 384 cases (or spouses, for deceased cases), and compared their responses with those of 876 controls. We classed distilled liquors as dark or light, a rough division according to content of potentially carcinogenic compounds in the beverages. The relative effect on hypopharyngeal cancer risk was much stronger for those who reported high consumption of dark liquor (relative risk = 4.4, 90% confidence interval = 2.9, 6.8) than for those reporting comparable consumption of light liquor (relative risk = 1.3, 90% CI = 0.8, 2.1). For laryngeal cancer, consumption of dark liquor had a smaller effect, and there was little distinction between the effects of dark and light liquor. The data appear consistent with the theory that the non-alcoholic content of distilled alcoholic beverages is a determinant of cancer risk, and that alcoholic beverages act topically rather than systemically in their carcinogenic action. (*Am J Public Health* 1989; 79:1516–1520.)

Introduction

Alcohol consumption is carcinogenic to most of the tissues in the upper aerodigestive tract, including the larynx, pharynx, and mouth.[1–6] Little is known, however, about the mechanism for alcohol carcinogenicity. The effect of alcohol on cancer risk appears greater for tobacco smokers than for non-smokers,[7] and some have questioned whether alcohol consumption is carcinogenic among nonsmokers.[8] Theories about the mechanism of alcohol carcinogenesis include the possibility that alcohol has a topical action, acting as a solvent for carcinogenic compounds, possibly enhancing their penetration through mucosa[8,9]; that alcohol consumption alters the nutritional balance and consequently leads to reduced consumption of dietary preventives that act through a central mechanism on epithelial cells[8,10,11]; and that alcohol directly affects metabolism in a way that increases the susceptibility of certain mucosal cells to cancer.[8] If alcohol acts as a solvent, its carcinogenic effect should be greater among smokers than among non-smokers. In addition, alcoholic beverages that come with already dissolved carcinogens should be more carcinogenic than alcoholic beverages free of such ingredients. This latter effect should be more easily measured among non-smokers, since smokers may inhale enough carcinogens in smoke to overwhelm the possibly smaller effect of carcinogenic substances in the beverages themselves.

Various carcinogens or potential carcinogens have been detected in alcoholic beverages. Beer, for example, has been reported to contain nitrosodimethylamine.[12] Scotch whisky is made by exposing sprouted barley to the smoke of burning peat,[13,14] and many spirits, including bourbon, dark rum, and rye are aged in charred oak barrels.[14] Cognac is aged in limousin oak barrels from which the beverage acquires a high tannin content.[14] Tannin is reportedly carcinogenic in both rats and mice following subcutaneous injection.[15] Despite the presence of these carcinogens in alcoholic beverages, it is uncertain whether the type of alcoholic beverage is an important determinant of cancer risk. For this investigation, we restricted our attention to distilled alcoholic beverages, which have the highest concentrations of alcohol, and evaluated the comparative carcinogenic effects of dark liquor versus light liquor. We classed all whiskeys, dark rum, and cognac as dark liquors, and vodka, gin, and light rum as light liquors. Dark liquors as a group contain much higher concentrations of organic compounds that include higher alcohols, esters, and aldehydes and other congeners.[16] Light liquors are highly distilled alcoholic beverages that are comparatively free of additional chemicals. Many vodkas, for example, are nearly pure ethanol solutions.[16]

Methods

The study population comprised all residents of the Boston Standard Metropolitan Statistical Area during the period January 1, 1982 through December 31, 1984. We prospectively identified cases of laryngeal and hypopharyngeal cancer that were diagnosed in the study population during the study period with the cooperation of 119 otolaryngologists in the area. We would have liked to include cases of mouth cancer in the study, but the otolaryngologists who were our major source for case ascertainment did not see in their practices a high enough proportion of the mouth cancer cases occurring in Greater Boston, whereas they saw the great majority of cases of laryngeal and hypopharyngeal cancer. Before the study, we wrote to all otolaryngologists and head and neck surgeons in Greater Boston and surrounding communities (as far as Worcester); during the study period we continued to approach new practitioners for their cooperation. In all we asked 214 otolaryngologists and head and neck surgeons to cooperate, of whom 119 agreed. Most of the physicians who did not cooperate, some of whom were retired or semi-retired, saw few cancer patients, so that the proportion of potentially eligible cases who were ascertained through physicians' practices is far greater than the proportion of cooperating physicians. We contacted all cooperating physicians monthly to learn of any newly diagnosed eligible cases. All cases had to have a histologically confirmed diagnosis of cancer of the larynx or hypopharynx. We sought written permission from the responsible physician to contact each eligible case.

As an independent source of case ascertainment, we included all cases of laryngeal and hypopharyngeal cancer recorded by the Massachusetts Cancer Registry. The Massachusetts Cancer Registry is a population-based registry to which all hospitals and clinics are required to report all cancer cases, excluding certain skin carcinomas. (At the time that we began this study, the Registry was new and was not an

© 1989 American Journal of Public Health 0090-0036/89$1.50

adequate source by itself for case ascertainment.) For each case identified by the Registry, we approached the responsible physician and obtained written permission to contact the patient, if the patient had not been identified previously.

For each case identified, we randomly selected as control subjects up to three people from the listing of residents of the same town as the case. These listings are published by each town under state law; with them we were able to ascertain conveniently a geographically representative series of controls that had roughly the same age and sex distribution as the cases. The process called for randomly identifying a place in the town book, and from that place identifying the next resident of the same sex born in either the same calendar year as the case subject or one year earlier or later. This step was repeated for each control subject. The matching criterion for year of birth was relaxed slightly for cases 70 years of age or over. To be eligible, controls had to be alive and still residing in the same town as the case at the time that we attempted to contact them. Many of the potential control subjects that we identified, upon investigation, were not alive; in these instances we continued to pick names from the town listing until we reached a maximum of three controls per case. (Toward the end of data collection, to avoid prolonging the study, we did not seek a full set of three controls for each case.)

All cases and controls received an introductory letter that stated in general terms that we were conducting a health study and desired to arrange an interview. The subjects were then contacted, usually by telephone, to arrange a personal interview conducted by trained study personnel. Those subjects who agreed were interviewed at home using a completely structured interview form. The interviewers were not told that the specific focus of the study concerned alcoholic beverages. The interview covered demographic data, medical history, occupational history, tobacco intake, certain dietary factors, drugs, mouthwashes and gargles, and other items. We obtained detailed data about timing, intensity, and type of exposure to alcoholic beverages and tobacco products. Nearly all interviews were conducted in English; three were in Spanish. For cases who had died or were unable to communicate owing to recent laryngeal surgery, interviews were conducted with the help of a spouse or with the spouse directly. One interview was conducted with the mother of a case, with whom the subject lived all his life except during military service.

For the stratified analyses, the estimation of relative risk (RR) across several strata was performed using maximum likelihood techniques to estimate the common odds ratio.[17]

Results

We identified 679 eligible cases, of whom 425 were ascertained directly from the cooperating physicians, and 254 were ascertained later through the Massachusetts Cancer Registry. We attempted to contact 625 of these cases, and could locate 604. No contact was attempted for 29 because the responsible physician was not cooperating with the study; for 20 because the physician's office requested that we not include the patient in the study; and for five cases, ascertained through the Veterans Administration, because there was no response to several requests from the responsible physician for consent by the patient to include him or her in the study. Of the 604 cases located, 42 were too ill for us to interview. An additional 128 patients had died before we contacted them. Of these 128, we obtained an interview with the spouses of 27, but 71 left no surviving spouse, 12 spouses were not available or did not respond, 10 spouses refused to be interviewed, and eight cases were identified through the Veterans Administration, which did not permit us to contact the surviving spouse. An additional 77 cases refused to participate, eight because of language problems. The total number of cases or spouses who were interviewed was 384; 18 of these interviews were with spouses of living cases who could not communicate readily, and one was with the mother of a case. The "response rate" among cases may be calculated in various ways. Of the 679 originally identified cases, only 57 percent are included among those interviewed, but this group represents 82 percent of those for whom an interview was possible (604 located cases minus 42 who were too ill, 83 who died with no spouse to contact, eight for whom we were not allowed to contact the spouse, and eight with language difficulties).

We identified 2,312 potential control subjects. We received no response to our initial letter addressed to 721 of these people. Many of these, however, no longer lived at the listed address when we attempted contact, or had died. The total, therefore, includes the names of an uncertain number of subjects who were not actually eligible for inclusion as a control. We were able to locate 1,591 of the potential controls; of these, 27 did not participate because of language problems, and 588 did not participate for various other reasons. We interviewed 883 controls, of whom seven gave interviews that we considered unreliable and did not use. The proportion of located controls whom we interviewed (55 percent) is lower than we would have liked, and reflects the increasing difficulty of obtaining cooperation for general population studies.[18]

The most important risk factors to consider as potential confounding factors in a study of laryngeal and hypopharyngeal cancer are age, sex, alcohol consumption, and tobacco use. Total alcohol consumption may be regarded as a possible confounder of the non-alcoholic component of dark or light distilled liquor consumption. Tobacco use may not only confound, but also modify an alcohol effect. Occupational risk factors for these cancers have also been reported, but these risk factors affect only small proportions of the population, and should not be strongly related to type of alcoholic beverage consumed, so that confounding from occupational risk factors was not a concern in this analysis. Socioeconomic status is not a strong risk factor conditional on total alcohol consumption and tobacco use.

We first examined the relation between cancer occurrence and the maximum amount of either dark or light liquor consumed weekly at any time. For analysis, we categorized subjects into three levels of maximum consumption (one drink per week or less, two-six drinks per week, and seven or more drinks per week), and compared those in the highest category with those in the lowest. The crude RR for drinking seven or more drinks per week of light liquor, relative to one or less, was estimated to be 1.7, with a 90 percent confidence interval (CI) of 1.3, 2.3. Controlling sex and age by stratification and calculating the maximum likelihood estimate of a common odds ratio indicated that despite the matching (which can introduce confounding) there was no confounding by these factors. We defined tobacco use in terms of pack-years of cigarette smoking (one pack-year equals 7,305 cigarettes smoked), or pack-year equivalents, based on comparable amounts of tobacco consumed, for cigar, pipe and cigarillo smokers and users of smokeless tobacco. We considered one cigar the equivalent of five cigarettes; one

pipeful, one plug, or one cigarillo the equivalent of two cigarettes. For these analyses we divided total tobacco use into two categories, those who reported less than 25 pack-years ("light" smokers) and those who had reported at least 25 pack-years ("heavy" smokers). Finer stratification of smoking produced intolerably small numbers within strata, and the consistently heavy smoking of laryngeal cancer cases precluded using a category boundary less than 25 pack-years. This stratification diminished the point estimate for light liquor consumption slightly, to 1.5. We then controlled simultaneously for tobacco and for the total amount of alcohol consumed; we estimated the total lifetime consumption of ethanol, including beer, wine, and other sources, and we then categorized the total into three levels: fewer than 1,000 drinks, 1,000–14,999 drinks and 15,000 or more drinks. One drink was equivalent to one shot (1½ ounces) of distilled liquor, 12 ounces of beer, and five ounces of wine. Control of tobacco and total alcohol consumption reduced the effect of light liquor consumption, comparing the highest level with the lowest, to an estimated RR of 1.1 with a 90% CI 0.8, 1.5.

The crude RR of consuming seven or more drinks per week of dark liquor, relative to one drink per week or less, was estimated to be 2.6, 90% CI 2.0, 3.2. This value was essentially unchanged after controlling for age and sex by stratification. Controlling for pack-years of tobacco use, however, reduced the point estimate to 1.9, 90% CI 1.5, 2.4. Controlling additionally for total lifetime alcohol consumption reduced the effect estimate to a RR of 1.3, 90% CI 1.0, 1.7.

The difference in effect estimates for the maximum rate of consumption of dark versus light liquor is relatively modest; nevertheless, even after control of confounding by tobacco and total alcohol consumption, there was some indication of a possible carcinogenic effect for dark liquor that did not exist for light liquor.

Cases were classified according to site of tumor into three major categories, hypopharyngeal (84 cases), supraglottic (125) and glottic (175), and the above analyses were repeated for each anatomic site separately. There were no cases of subglottic cancer among the 384 cases interviewed. These results are summarized in Table 1. The effects of dark liquor and light liquor appear similar for the supraglottis and glottis, but dark liquor appears to increase the risk of hypopharyngeal cancer whereas light liquor does not.

To determine whether the effect of dark liquor varied according to level of tobacco use, we examined the effects of drinking various quantities of light and dark liquor separately for light and heavy tobacco users. The distribution of cases for each type of cancer, and controls, is given by the maximum weekly intake of dark liquor and by category of tobacco use in Table 2. There is an increasing pattern of risk for greater maximum weekly consumption of dark liquor for both tobacco-use categories. The trend is again concentrated among hypopharyngeal cases (although it is unstable owing to the small number of cases among those with fewer than 25 pack-years of tobacco use). The joint effect of tobacco use and heavy consumption of dark liquor appears substantially greater than additive for the hypopharyngeal cases. This observation is based on a comparison of the highest versus lowest category of liquor consumption for each of the tobacco categories: the difference is 16.7 in the high-use category and 5.0 in the low-use category. The small number of cases in the latter category affects this comparison also, making the evidence for interaction in these data tentative.

We then conducted multivariate logistic analyses to examine the effects of dark and light liquor consumption in the same analysis. Conditional logistic models, which control for the matching variables of town, age and sex, gave results similar to the corresponding unconditional logistic models,[17] and are not reported. These analyses provided the efficiency to evaluate three levels of consumption of dark and light liquor simultaneously. We categorized subjects according to total number of drinks of dark or light liquor consumed during the subject's lifetime, which we calculated from the detailed histories that we obtained. We used categories of fewer than 200, 200–4,999, and 5,000 or more drinks; those who consumed fewer than 200 drinks formed the referent category. Although the total number of drinks is a function of age, age was found not be confounding, nor was sex, and these variables were therefore omitted from the regression models presented here. The model in Table 3, with terms for two levels of dark and light liquor consumption (in addition to the implied referent category), indicates an association with cancer risk of heavy consumption of dark liquor, and a smaller association for heavy consumption of light liquor. The comparable model restricted to hypopharyngeal cases (Table 4) shows a much stronger effect of heavy consumption of dark liquor and no material association for light liquor consumption. When terms for total alcohol consumption are added to the models in Tables 3 and 4, the effect of heavy consumption of dark liquor is smaller, but some effect

TABLE 1—Relative Risk Estimates for Consuming Seven or More Drinks per Week of Light and Dark Liquor, Relative to Consuming One Drink or Less, with 90% CI, for Three Anatomic Sites, Controlling for Tobacco Use and Total Alcohol Consumption

	Light Liquor		Dark Liquor	
Anatomic Site	RR	90% CI	RR	90% CI
Hypopharynx	1.0	0.6, 1.7	1.6	1.0, 2.5

				1.0	1.4[b]	3.4[b]
RR (larynx cases)	1.0	1.4[a]	0.9[a]	5.2[a]	5.2[a]	8.0[a]
				1.0	1.0[b]	1.5[b]

[a]Risk ratio with the low-tobacco, low-alcohol category as the referent.
[b]Risk ratio with the high-tobacco, low alcohol category as the referent.

TABLE 3—Relative Risk Estimates and 90% CI for Dark and Light Liquor Consumption in a Multiple Logistic Regression Analysis

Variables	Coefficient	Standard Error	RR Estimate	90% CI
Dark Liquor (200–4,999 drinks)	0.343	0.193	1.41	1.03, 1.94
Dark Liquor (5,000+ drinks)	0.854	0.141	2.35	1.86, 2.96
Light Liquor (200–4,999 drinks)	−0.680	0.234	0.51	0.34, 0.74
Light Liquor (5,000+ drinks)	0.462	0.174	1.59	1.19, 2.11

remains, whereas there is no effect of heavy consumption of light liquor conditional on total ethanol consumption. Table 5 gives the model with total alcohol consumption for hypopharyngeal cases.

We examined the influence of dark liquor consumption for various time periods before the cancer was diagnosed on hypopharyngeal cancer risk. These analyses indicated that consumption of dark liquor within the 10 years preceding diagnosis was much less strongly related to occurrence than was consumption in earlier decades.

Discussion

Methodologically the greatest concern in this study is the response rate, especially that of controls. Only 55 percent of the located controls were interviewed, and an unknown number of eligible controls were not located, in part because many of our subjects came from neighborhoods with high population turnover. The concern is that the subjects actually interviewed could have had exposure histories that differ from those not interviewed, possibly because the exposure is directly or indirectly related to the sequence of steps leading to inclusion in the study. Were the study focusing on total alcohol consumption, this concern would be intensified, since it is easy to image that the amount of alcohol consumed could affect the likelihood of participation. For the exposure of interest, however, which is the type of distilled alcoholic beverage consumed, we conjecture that selection bias from non-participation is a less serious problem. An important bias would have to involve marked selective participation among controls for consumers of dark liquor relative to light liquor or vice versa, independently of the total amount of alcohol consumed. Although there may be social class differences among liquor types that might introduce an association between beverage preference and the decision to participate in the study, the magnitude of these associations would have to be very strong to introduce a worrisome degree of bias into the comparisons reported here.

TABLE 4—Relative Risk Estimates and 90% CI for Dark and Light Liquor Consumption in a Multiple Logistic Regression Analysis (Hypopharyngeal Cases Only)

Variables	Coefficient	Standard Error	RR Estimate	90% CI
Dark Liquor (200–4,999 drinks)	0.396	0.407	1.49	0.76, 2.90
Dark Liquor (5,000+ drinks)	1.483	0.2631	4.40	2.85, 6.78
Light Liquor (200–4,999 drinks)	−0.385	0.405	0.68	0.35, 1.32
Light Liquor (5,000+ drinks)	0.237	0.311	1.27	0.76, 2.12

TABLE 5—Relative Risk Estimates and 90% CI for Dark and Light Liquor Consumption in a Multiple Logistic Regression Analysis Controlling Alcohol Consumption from All Sources (Hypopharyngeal Cases Only)

Variables	Coefficient	Standard Error	RR Estimate	90% CI
Dark Liquor (200–4,999 drinks)	0.019	0.422	1.02	0.51, 2.04
Dark Liquor (5,000+ drinks)	0.559	0.284	1.75	1.10, 2.79
Light Liquor (200–4,999 drinks)	−0.559	0.405	0.57	0.29, 1.11
Light Liquor (5,000+ drinks)	−0.136	0.308	0.87	0.53, 1.45
Total Alcohol (1,000–14,999 drinks)	1.522	0.671	4.58	1.52, 13.8
Total Alcohol (15,000+ drinks)	2.635	0.632	13.9	4.93, 39.4

Another potential concern is the use of surrogate interviews for 12 percent of cases. Cases who were deceased were included if a spouse could be interviewed. We also interviewed the spouses of 18 cases who had difficulty communicating. Spouse interviews presumably vary in accuracy depending on the information sought. The recent history of tobacco use, alcohol use, and other factors of interest is likely to be more accurate than early use. Alcohol consumption, which sometimes occurs without complete spousal awareness, may be particularly susceptible to error in spousal interviews. Here again our focus on type of beverage more than on amount mitigates the potential bias.

We used no surrogates for controls, since controls had to be alive to be eligible. Technically, since controls were matched individually to cases, controls who were alive at the time that the case was diagnosed should be eligible, regardless of whether they died before we attempted to contact them. Our decision not to include such individuals was motivated by convenience; it presents little problem if we can assume that there is no important departure from a dynamic equilibrium in the prevalence of type of distilled alcoholic beverage consumed.

Because all the exposure information in this study was reported by the subjects, there is presumably a substantial amount of misclassification. Some of the misclassification stems from faulty recall, and some from simplifying assumptions that we could not avoid in constructing summary measures of exposure. To the extent that such misclassification is comparable for cases and controls, the effect estimates in this analysis are underestimates of the actual effects.

The carcinogenic effect of alcoholic beverages is already well established.[19–21] When controlling for total alcohol consumption, which permits the evaluation of the effect of the non-alcohol component of alcoholic beverages, the additional cancer risk estimated for heavy consumption of dark liquor is modest.

What is important to note in these findings, however, is the divergent pattern of risks for upper airway cancer experienced by heavy consumers of dark liquor and heavy consumers of light liquor among hypopharyngeal cases. The site localization and the differences in effects between light and dark liquor are predicted by the theory that the carci-

nogenic action of alcohol is mainly topical, rather than systemic, and that the role of alcohol is to act as a solvent for other carcinogens, increasing the penetration of these carcinogens into epithelial tissue. The interactive effect with tobacco use that was observed is also consistent with this theory. These findings, on the other hand, are difficult to reconcile with alternative theories of alcohol carcinogenesis that suggest that ethanol increases carcinogenic risk through central rather than topical mechanisms.[8]

ACKNOWLEDGMENTS

Many people contributed to this effort. The cooperation of the numerous surgeons who allowed us to intrude upon their office routines was essential to us, and we are indebted to them all. The Massachusetts Tumor Registry greatly facilitated our case ascertainment; we are especially grateful to Richard Clapp for his encouragement and assistance. Noreen Manzo, Brenda Birmann, and Elizabeth Grover contributed outstandingly to the administration of the data collection and analysis. We received helpful comments from William Blot, Deborah Winn, Charles Poole, and Stephan Lanes. This work was supported by PHS grant number CA38455, awarded by the National Cancer Institute, DHHS.

'Children and Hospitals Week' Designated for March 25–31, 1990

A public awareness campaign focusing on the special needs of children and families in health care settings will be held March 25–31, 1990 throughout the United States. Designated "Children and Hospitals Week," the nationwide activity will feature health fairs, hospital open houses, preparation programs, "Teddy Bear" Clinics, library and school exhibits, educational conferences, and hundreds of other events. The theme for the week is "Commitment to Caring."

Communities and organizations who wish to participate in the Children and Hospitals Week can send for a free Planning Guide, which includes ideas for activities, publicity, and fund raising. The planning guide is available from:

Association for the Care of Children's Health (ACCH)
3615 Wisconsin Avenue, NW
Washington, DC 20016
(202) 244-1801

ACCH is a multidisciplinary organization devoted exclusively to the psychosocial well-being of children and families in health care settings.

Prevention of Childhood Injuries: Evaluation of the Statewide Childhood Injury Prevention Program (SCIPP)

BERNARD GUYER, MD, MPH, SUSAN S. GALLAGHER, MPH, BEI-HUNG CHANG, MS, CAREY V. AZZARA, MA, L. ADRIENNE CUPPLES, PHD, AND THEODORE COLTON, SCD

Abstract: We evaluated the effectiveness of a community-based injury prevention program designed to reduce the incidence of burns, falls in the home, motor vehicle occupant injuries, and poisonings and suffocations among children ages 0–5 years. Between September 1980 and June 1982, we implemented five injury prevention projects concurrently in nine Massachusetts cities and town; five sites, matched on selected demographic characteristics, were control communities. An estimated 42 percent of households with children ages 0–5 years were exposed to one or more of the interventions over the two-year period in the nine communities. Participation in safety programs increased three-fold in the intervention communities and two-fold in the control communities.

Safety knowledge and practices increased in both intervention and control communities. Households that reported participatory exposure to the interventions had higher safety knowledge and behavior scores than those that received other community exposure or no exposure to intervention activities.

We found a distinct reduction in motor vehicle occupant injuries among children ages 0–5 years in the intervention compared with control communities, associated with participatory exposure of about 55 percent of households with children ages 0–5 years. We have no evidence that the coordinated intervention programs reduced the other target injuries—although exposure to prevention messages was associated with safety behaviors for burns and poisonings. (*Am J Public Health* 1989; 79:1521–1527).

Introduction

Injuries are the leading cause of death and a major cause of serious morbidity and disability among children and youth.[1] Yet, there have been relatively few efforts to carry out controlled community prevention trials. Schlesinger, *et al*, evaluated a health education program for families with children less than 7 years of age in a study community using a matched community as a control, but found no reduction in medically attended injuries.[2] The other population-based intervention trials reported have focused on the prevention of specific injury types, such as burns[3,4] and pedestrian injuries.[5,6] We evaluated the effectiveness of the Statewide Childhood Injury Prevention Program (SCIPP)—a community-based injury prevention program designed to reduce the incidence of burns, falls in the home, motor vehicle occupant injuries, poisonings, and suffocations among children ages 0–5 years. Our rationale was that by combining the safety interventions available at the time we could reduce childhood injury rates.

Methods

Study Design

The investigation involved concurrent implementation of five injury prevention projects in nine Massachusetts cities and towns with a total population of 139,810 persons and selection of five control communities with a population of 146,866, matched on demographic characteristics to the intervention communities. The injury prevention projects commenced in September 1980 and continued for a 22-month period, through June 1982. A surveillance system to collect data on incident cases of childhood injuries was established in September 1979, one year before the intervention began, and was maintained throughout the study period to August 1982.[7] Telephone surveys of attitudes, knowledge, self-reported safety practices, and exposure to injury prevention projects were completed before the beginning of the interventions in August 1980 and again after their completion in August 1982.

Intervention Methods

Five intervention programs were selected:

- injury counseling for the parents of young children by pediatricians using the developmentally based Framingham Safety Surveys[8];
- school and community burn prevention education using the Project Burn Prevention curricula[4];
- household injury hazard identification and control through systematic home safety inspections by specially trained local board of health staff[9];
- community-wide promotion of the Massachusetts Poison Control System's telephone information service and public education about poison prevention[10,11]; and
- promotion of child automobile restraint use, particularly for children in preschools and infants leaving maternity hospitals.

The primary target injuries, target age groups, and components for each project appear in Appendix A. The principal focus was families with children ages 0–5 years. Implementation of the projects occurred at health and educational institutions that already served children and their families in the study communities. The five prevention programs were integrated in the same study communities to reinforce each other's preventive messages.

Site Selection

The site selection process involved comparison of data on all 351 cities and towns in Massachusetts for: population

size and density, age composition, education level, family income, housing characteristics, hospital usage patterns, and characteristics of local pediatricians, school districts, and boards of health,[12–16] and informal information supplied by an advisory committee. The sites were grouped into two comparable sets of intervention and control communities. Details have been published previously.[7]

Measurements

The unit of intervention of this study was the community. Therefore, we evaluated the program's effects on the level of safety knowledge and practices and on the incidence of childhood injuries in the study and control communities with counts of project participants, pre- and post-intervention telephone surveys, and a hospital-based injury surveillance system.

Injury Prevention Project Activities: Reports from each intervention project provided counts of the numbers of persons and households reached and materials distributed. We also conducted a post-intervention telephone survey in August 1982 to estimate exposure to interventions over the preceding two years.

Telephone Surveys: We conducted telephone surveys in both intervention and control communities with use of a random digit dial methodology[17]: pre-intervention in August 1980 (1200 respondents) and post-intervention in August 1982 (914 respondents). The primary criterion for selection into the sample was that at least one child 19 years old or younger lived in the household. The surveys included 95 items that assessed a household's exposure to an intervention (e.g., home visited by a housing inspector), and self-reported safety behavior and knowledge.

In addition, prevention behaviors were measured. We grouped responses to behavior-related questions on the survey to form an index of prevention behavior for each of three injury causes: poisonings (14 items), burns (12 items), and falls (6 items). A committee of injury prevention professionals assigned weights to items within each index and adjusted the weights to produce a scale score of 0–100 points[18] (Appendix B). We used the safety scores as outcome measures. A question concerning the use of auto passenger restraints by children was analyzed as a separate variable.

We used parental responses to questions about exposure to each injury prevention intervention to classify households into one of three hierarchical levels: 1) no exposure; 2) community exposure, i.e., the family received general injury prevention information, such as pamphlets, from a community source; or 3) participatory exposure, i.e., the family received specific intervention materials, direct person-to-person counseling, or modifications of a household hazard from at least one SCIPP-funded or related project. We classified households by their greatest degree of exposure to any one intervention. Participatory exposures could have been provided by our own projects or those of other community agencies.

Injury Surveillance: The sampling plan and operational characteristics of the injury surveillance system have been described elsewhere.[7] Briefly, we defined cases as children and adolescents (ages 0–19 years) who resided in one of the 14 communities and who had an injury that required medical treatment at an emergency room, admission to a hospital, or resulted in death. We recorded injury cases at 23 hospitals that provided care for an estimated 93 percent of all pediatric injuries in the population.

The five target injuries for intervention efforts were motor vehicle occupants; poisonings due to medicinals and household products and plants; burns; falls from stairs, ladders, other building structures and furniture; and suffocation from objects.

Statistical Analysis

Changes in Knowledge and Practices: We assessed differences between pre- and post-intervention telephone survey responses for the intervention and control communities by means of the safety scores for burns, poisonings, and falls in the home and the responses to the motor vehicle restraint behavior question. Since the two surveys consisted of different respondents, we conducted a two-factor analysis of covariance (ANCOVA) with socioeconomic status (SES) as the covariate, using the SAS PC computer statistical package.[19] Green's SES score constituted the measure of SES in this analysis.[20] The two factors were the community effect (control vs intervention sites) and the time effect (pre- vs post-intervention). We construed an interaction effect between the two main effects as evidence of differential patterns of safety by community type and time of measurement. A statistically significant interaction would need further investigation with use of post hoc comparisons to determine whether the pattern of interaction revealed an impact of the prevention programs in the study communities.

Effects of Exposure on Knowledge and Practices: We used the nature of exposure (no exposure, community exposure, and participatory exposure) as the main factor in a one-factor ANCOVA with SES as the covariate; the safety indices for poison, burns, and falls in the home were the dependent variables. For motor vehicle occupant behavior, we evaluated the association between nature of exposure (exposed or not exposed) and response to the survey question about child use of auto restraints by chi-square and logistic regression that adjusted for SES.

Changes in Injury Incidence: We compared age-specific injury rates in the pre-intervention period (approximately one year) to the during-intervention period (approximately 22 months) in the control and intervention communities. The post-intervention period was too brief to analyze. We computed Cochran-Mantel-Haenszel (CMH)[21] statistics to test the association between the rate changes (pre- to during intervention) and community type (control or intervention) with control for SES. The measure of SES used in this analysis was median family income of the community, which we stratified into three levels to achieve groups of roughly similar size: less than $20,000, $20,000–25,000, and more than $25,000. Within each combination of age group and injury type, we established a 2 × 2 contingency table.

Results

Exposure to Interventions

During the 22-month period of intensive intervention in the nine intervention communities, direct counts of participation showed that an estimated 42 percent of households with children ages 0–5 years participated in the activities of the SCIPP prevention projects. Pediatric counseling, which included a strong child auto seat component, reached 21 percent of households with children ages 0–5 years; child auto passenger safety programs reached 17 percent; Project Burn Prevention in the community reached 10 percent; home hazard inspection reached 5 percent; and the poison control system reached 1 percent.

We obtained completed telephone surveys for 1,200 households in the pre-intervention survey and 914 in the post-intervention survey; in all we reached the mothers of 4,351 children ages 0–19 years, about 5 percent of all children in the 14 communities. Success in completion of surveys for eligible telephone numbers varied from 59 percent in the pre-intervention survey, when we made only five call-backs, to 85 percent in the post-survey when we made up to 10 call-backs, but did not differ between intervention and control communities. The refusal rate for eligible households was 9.8 percent in the pre-intervention survey and 6.0 percent in the post-survey. The demographic characteristics of the interviewee samples were similar. For the purposes of this evaluation, we used only those households with children ages 0–5 years.

Table 1 shows that even prior to the beginning of the program, households in both study and control communities were exposed to childhood safety messages by a variety of means. We found no significant differences in pre-intervention safety exposures between intervention and control communities.

Over the course of the intervention, the level of participatory exposure for households with children 0–5 years increased three-fold in the intervention communities and two-fold in the controls. Overall, intervention communities' had a higher percentage of participatory exposure than control communities, 62.4 percent vs 38.2 percent (95% confidence intervals of difference 13.9, 34.5). Similar differences hold for participatory exposure in all five target injuries (Table 1).

Changes in Safety Knowledge and Practices

The SES-adjusted mean safety scores for burns- and falls-related behaviors increased from the pre- to post-intervention survey to the same extent in both the intervention and control communities (Table 2) The poisoning safety index showed some effect of exposure. We found no interaction effects for any of these indices.

Effects of Exposure to Interventions on Knowledge and Practices

We found an association between level of participation and safety behaviors for burns and poisoning but not for falls (Table 2).

For the auto restraint use variable, we evaluated only two exposure groups (exposed and non-exposed). Reported use of child auto restraints was 22.2 percent–higher in households that had exposure to prevention programs than in households not so exposed (Table 2). To hold the effects of SES constant, we computed the logistic regression of the probability of reporting restraint use on exposure status and SES. The coefficient for exposure status was 0.47 ($\chi^2 = 31.2$, $p = 0.0001$). With employment of methods commonly used in econometrics to calculate the first derivatives of the logistic regression function,[22] the difference between exposed and non-exposed households in reported child restraint use adjusted for SES reduces to 11.6 percent.

Changes in Injury Incidence

Figure 1 shows the pattern of injury incidence rates for target injuries sustained by children ages 0–5 years in the intervention and control communities over the three-year period. At every point, the incidence rate for intervention communities is lower than that for controls. This difference reflects the difference in SES between the intervention and control communities and disappears with adjustment of the rates for SES.

The crude incidence rates for specific target injuries for children ages 0–5 years appear in Table 3. The overall incidence for all target injuries increased in both intervention and control communities from the pre- to the during-intervention period. In the intervention communities, however, the incidence of motor vehicle occupant injuries decreased 54 percent, while rates rose in the control communities. With control of SES, the odds in favor of a motor vehicle occupant injury in the pre-intervention period versus the during-intervention for the intervention communities was 2.78 times as large as that for the control communities.

Discussion

The principal positive finding of this study is a distinct reduction in motor vehicle occupant injuries among children

ages 0–5 years in the intervention compared with control communities. This finding is associated with evidence that about 55 percent of households with children ages 0–5 years participated in the interventions. Because many factors may have influenced the use of child auto restraints, however, the observed decrease in motor vehicle occupant injuries cannot be attributed to SCIPP alone. We have no evidence that the coordinated intervention programs reduced the other target injuries—although exposure to prevention messages was associated with safety behaviors for burns and poisonings. These findings suggest three major issues: the design of injury prevention evaluations, the relationship between injury incidence and preventive efforts that alter safety knowledge and behaviors, and the efficacy of efforts to reduce childhood motor vehicle occupant injuries.

The study was designed with the community as the level of intervention and analysis. Because it was impractical to randomize communities, we attempted to match communities on socioeconomic and demographic characteristics with use of the most currently available census data, 1970; injury morbidity rates were unavailable. By 1980, however, the control communities differed demographically from the intervention communities, and had higher proportions of poor and Hispanic households. This demographic change was reflected in higher baseline injury rates in the control communities, a finding which is in itself important. We addressed this problem by controlling for SES in all analyses.

Exposure to injury prevention messages occurred from sources other than our project. The media promoted childhood safety as did the pediatric and public health literature[23–25]; schools introduced safety curricula into their health education programs; the Massachusetts Legislature was debating a child auto restraint bill which, no doubt, led some motivated families to purchase these devices. This exposure of control sites introduced an element of misclassification into the comparison of intervention and control communities. It would have been impossible, however, to have eliminated these sources; estimating the magnitude of their effect on the findings is indeed difficult.

Evaluation of the effect of an intervention depends on the case definition of an injury and the method of ascertainment. We used an emergency room visit as the definition of the least severe injury. It is possible that some of our prevention messages may have altered the level of injury severity and use of the emergency room. For example, knowledge of the use of cold water following a scald burn might have reduced sufficiently the severity of burns so as to avoid hospitalization. Moreover, differential access to treatment by area of residence and socioeconomic status may have influenced ascertainment of cases.

High baseline levels of safety behaviors influenced our ability to show community effects. For example, our pre-intervention survey found that 73 percent and 69 percent of households in study and control communities, respectively, had smoke detectors. At the end of the study period, this level had changed to 82 percent and 84 percent, respectively. Given the low incidence of burns associated with house fires, the study did not have adequate power to evaluate this change. In other cases, the level of exposure to an intervention may have been too low to demonstrate an effect. For example, household inspection and correction of hazards is a highly efficacious intervention,[9] but we reached only 5 percent of all target households in this trial. These design considerations emphasize the importance of using injury morbidity rates by cause at the local level to influence the selection of community sites, target injuries, and intervention strategies.

Finally, the study design did not permit us to disaggregate the changes in knowledge and behavior by the type of intervention strategy. We cannot comment on the relative efficacy of patient counseling by pediatricians, school edu-

TABLE 3—Changes in Target Injury Rates for Children Ages 0–5 Years in Intervention and Control Communities

Target Injuries	Injury Rates[a]				Mantel-Haenszel Odds Ratio[b]

c)Total target injuries include a small number of suffocations on objects other than food.

cational curricula, community promotion, or home inspection as the technique to best influence behavior. Different intervention techniques will likely have different effects, and these need further study.

We do know that there were several components to the efforts to reduce motor vehicle occupant injuries. These included promotion by pediatricians of infant and child auto restraint utilization, an in-hospital training program for health professionals and car seat loan programs, establishment of a Child Auto Passenger Safety Resource Center at the state health department with community presentations for parents and providers at preschools and other settings, and statewide advocacy for a mandatory child restraint law which was passed in December 1981. Participation in these activities combined with media attention may have increased safety behavior in the intervention communities as compared to the non-intervention sites. There is good evidence from studies of cardiovascular disease control programs that combined mass media and comprehensive community-based interventions can succeed in improving a community's health status.[26–28]

There is good reason to believe that the prevention technologies promoted through our educational efforts were of differing levels of efficacy. Thus, while we may have exposed our population to all the injury-specific messages equally, we observed a protective effect on auto occupant injuries, primarily, because the child auto restraint device is a highly efficacious technology, and auto crashes occur with sufficient frequency so that one can measure an effect.

Length of exposure to injury prevention efforts may be important to the success of community efforts such as SCIPP. We maintained the interventions and surveillance system for only 22 months because of limited resources. The benefits of changed safety knowledge and practices may manifest themselves more slowly and over a longer time frame. Schelp, in a community-based intervention in Sweden, showed decreases in injury rates after four years of activity.[29] In retrospect, our study was grossly underfunded given its ambitious nature.

Finally, we must acknowledge constraints in implementing "text-book" interventions in a real world setting. We cannot understate the logistics and difficulty of managing a set of complex interventions in several communities simultaneously. Our efforts to persuade local health agencies and community boards to take more of a lead role were thwarted by the unavailability of local morbidity data, a lack of financial incentives, and a lack of media attention to the injury problem. It may be that child auto injury was the only well-recognized injury issue.

In designing our project, we defined childhood injuries broadly and selected prevention methods from those available to us in 1979, when we had little evaluation data available. For example, the results of the evaluation of Project Burn Prevention were not available until 1982, when our intervention was nearly completed.[4] Our target injuries were limited by the availability of these interventions. Were we to redesign the SCIPP intervention today, we would look carefully at all the effective interventions discussed by Rivara[30] and others[31,*] and select only those that have strong evidence of efficacy. Future interventions must include the active participation of local public health agencies, a media component to increase the awareness of both the public and professionals, and evaluation over a longer time period. One must convince these local agencies of the importance of the injury problem, obtain their commitment of resources, and assure that the requisite local morbidity data are available for targeting injuries which are prominent in the community and for evaluation of the interventions.

ACKNOWLEDGMENTS

This work was supported by a grant (MCH 022001) from the US Department of Health and Human Services, Division of Maternal and Child Health to the Division of Family Health Services, Massachusetts Department of Public Health. Completion of the analysis and writing was supported by a grant from the Carnegie Corporation of New York and a grant (R49/CCR 102330) from the Centers for Disease Control to the New England Injury Prevention Research Center.

APPENDIX A

Injury Prevention Intervention

Intervention	Objectives	Targets	Components
Child Auto Passenger Safety Project	• To increase utilization of infant and child auto restraints • To reduce motor vehicle occupant injuries to children ages 0–5 years.	• Parents of newborns and young children • Health providers with access to maternity patients • Hospitals	• Survey of current hospital practices • In-hospital training of maternity and child birth educators • Resource Center for technical assistance • Promote car seat loan programs • Outreach to preschools • Observational study of restraint usage • Passage of mandatory child restraint law
Home Injury Prevention Project	• To reduce the number of hazards in the home environment • To incorporate injury prevention into traditional role of health agents • To reduce burns, poisonings, falls, and product-related injuries	• Families with children under age 5 years • High-risk housing • Landlords and homeowners	• Systematic enforcement of State Sanitary Code • Safety counseling to hazardous household practices • Distribution and installation of safety devices • Follow-up evaluation
Pediatric Accident Prevention Project	• To provide a developmentally-oriented, focused counseling system for pediatric primary care settings • To increase awareness and safety practices in parents of young children • To reduce burns, poisonings, motor vehicle injuries, falls, choking, and drowning	• Parents of children under age 5 years • Pediatricians • Well-baby clinics • Visiting nurses	• Age appropriate safety surveys • Counseling by health providers • Free safety supplies • Follow-up home assessment/evaluation
Poison Control System	• To promote appropriate treatment of the poisoned patient • To promote awareness and proper storage of poisonous substances	• Parents and older siblings of children under age 5 years • Hospital staff • Pharmacists Other retailers	• Promote emergency consultation care of poisoned patient • Educate health professionals • Promote poison information hotline • Promote availability of Ipecac • Mail surveys and site visits to pharmacies and other retailers • Free distribution of Ipecac displays, phone stickers and pamphlets
Project Burn Prevention	• To institute a burn prevention curriculum in schools • To increase awareness of burn hazards, escape from house fires, and clothing ignition • To reduce all causes of burns	• Parents of young children under age 5 years • School-age (4–18) children enrolled in public and private schools • Community groups	• Poster contest for grades K–2 • Train teachers in curriculum use • Free multi-media kits • Train volunteers • Promotion through libraries, fire & police, day care centers, civic organizations and youth groups • Follow-up evaluation

APPENDIX B

Telephone Survey Questions and Weights Used to Calculate Safety Indices for Burns, Poisonings, and Falls

Telephone Survey Questions	Weight
Poison Safety Index	
1. Store drugs/pain relievers on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is shoulder height?	2.6
2. Store drugs/pain relievers on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is locked?	20.8
3. Store drain cleaners on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is shoulder height?	5.2
4. Store drain cleaners on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is locked?	22.0
5. Store drain cleans in the original container?	4.2
6. Store liquid bleach on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is shoulder height?	2.0
7. Store liquid bleach on open shelf, in cabinet, in closet, in medical cabinet, or someplace else and the place is locked?	2.0
8. Never left bleach in a measuring cup?	2.2
9. Use kindergard latches on the cabinets?	2.8
10. The first response to poisoning is call poison control center for advice?	15.4
11. The first response to poisoning is call doctor/nurse for advice?	6.8
12. Have ipecac Syrup at home?	9.6
13. Have poison phone sticker posted and the number is 232-2120 or 1-800-682-9211?	2.4
14. Have poison phone sticker posted and the number *is other than* 232-2120 or 1-800-682-9211?	2.0
Total:	100.0
Burn Safety Index	
1. None of the cord of the electrical appliance hangs below the counter?	3.5
2. The best thing to put on burn is cool water?	8.6
3. Have a smoke detector in the building?	18.4
4. Have smoke detector installed in the bedroom hallway, or the basement, or all rooms?	14.6
5. Family has fire escape plan?	4.4
6. Family has tried fire escape plan?	5.6
7. Have safety plugs on electric outlets (yes/no question)?	2.0
8. Have safety plugs on *all* the outlets?	2.2
9. Have safety plugs on *some* of the outlets?	2.1
10. Do not have additional heat source at home?	3.7
11. The hot water temperature at home is 125 or below?	32.6
12. The fuses at home do not blow frequently?	2.0
Total:	99.7
Fall Safety Index	
1. Do not have broken window?	3.3
2. There are screens or barriers on window?	7.8
3. Have safety gates at either the top or bottom of the stairs?	26.3
4. Have safety gates at both the top and bottom of the stairs?	45.0
5. All the stairways in the building have railings?	14.3
6. None of the railings are unsteady?	3.3
Total:	100.0

Human Cryptosporidiosis Associated with an Epizootic in Calves

John S. Reif, DVM, MSc(Med), Lynne Wimmer, DVM, John A. Smith, DVM, MS, David A. Dargatz, DVM, MS, and John M. Cheney, DVM, MS

Abstract: An outbreak of human cryptosporidiosis occurred among previously healthy persons in a veterinary medical teaching hospital. Human illness began after admission of calves from a farm which had been experiencing an epizootic of neonatal diarrhea due to *Cryptosporidium*. The clinical syndrome in humans was characterized by watery diarrhea, abdominal cramping, flatulence, and headache. Cryptosporidiosis was confirmed by zinc sulfate flotation of fecal specimens in four persons, three of whom had been responsible for the care and treatment of infected calves. A fourth patient had washed her husband's soiled clothing and appeared to have been infected indirectly through fomite contamination. Among 112 persons surveyed, 26 (23.2 percent) had a diarrheal illness during the outbreak and nine met the case definition of a diarrheal illness lasting at least three days. These persons were more likely to have had contact with a calf with diarrhea than were 52 referents who did not become ill during the outbreak. (*Am J Public Health* 1989; 79:1528–1530.)

Introduction

Cryptosporidium is an intestinal protozoan parasite, recognized relatively recently as a human pathogen,[1] despite its original identification over 70 years earlier.[2] Following the description of the first human case of cryptosporidiosis in 1976, the disease was reported rarely, and primarily in immunocompromised persons.[3] Since 1982, the number of reported cases has increased dramatically.[4] Initially this increase was noted in patients with acquired immunodeficiency syndrome[5] but recent reports indicate that cryptosporidiosis also occurs in immunologically normal persons.[6–8] In immunocompetent persons, cryptosporidiosis is manifested as an acute, self-limiting diarrheal illness lasting five to six days.[4,6–8] Cases of cryptosporidiosis have been described in travelers,[9] residents of day care centers,[10] animal handlers,[8,11] veterinary students,[12–14] and following consumption of contaminated community water supplies[15] or surface waters.[16] A previous description of an outbreak of cryptosporidiosis among five veterinary medical students[13] was ascribed to contact with experimentally infected calves. Recently, infection of at least 10 students who had had contact with 1-to-3-day-old calves in a laboratory setting was described.[14] We report here an outbreak of cryptosporidiosis among previously healthy veterinary students associated with a spontaneous epizootic of bovine cryptosporidiosis in a clinical setting.

Methods

Outbreak in Humans

The index case was a 34-year-old female veterinary student whose duties included nursing care, sample collection, and treatment of calves with diarrhea which were subsequently identified as infected with cryptosporidia. On April 6, 1987, one week after her initial contact with the calves, she complained of watery diarrhea, abdominal cramps, nausea, fever (greater than 99°F), headache, vomiting and flatulence; she was ill for two weeks. She received medical attention and was found to have cryptosporidiosis after parasitologic examination of her stools.

During the next two weeks, several additional students and faculty members complained of gastrointestinal symptoms. A large proportion of these persons were associated with the food animal services. When cryptosporidia were identified in calves hospitalized in the isolation unit, a potential relationship between the animal and human diarrheal illnesses became apparent.

An investigation was initiated on April 17, 1987. A questionnaire distributed to all students and food animal hospital staff included items on recent gastrointestinal illness, and exposure to potential risk factors in the hospital and at home. Dates of potential exposure to calves in the isolation unit were determined from student duty rosters. Persons experiencing diarrheal illness and others with food animal contact were asked to submit stool samples.

Parasitologic examination for cryptosporidia oocysts consisted of fecal flotation by centrifugation of zinc-sulfate (sp. gr. 1.18) to which aqueous iodine had been added.[17] Cover slips from these flotations were examined by light and phase contrast microscopy. Fecal smears were examined after methanol fixation and Ziehl-Nielsen staining.[18] Analysis of risk for specific exposures was accomplished by calculation of odds ratios (OR) for persons experiencing a diarrheal illness, using those who remained clinically normal as the comparison group.[19] Confidence intervals (95% CI) for these risk estimates were obtained by exact testing.[20]

Epizootic in Calves

An outbreak of diarrheal illness in beef calves occurred on a farm in northern Colorado. Virtually all of the 91 calves born after February 1987 developed postnatal diarrhea. Newborn calves continued to develop diarrhea during the first week of life as the calving season progressed. Due to the continuing nature of the diarrheal disorder, four newborn calves with severe diarrhea and dehydration were admitted to the Veterinary Teaching Hospital on March 23, 1987 and placed in the isolation unit. Additional affected calves were admitted weekly until June 6. On April 16, 1987 a fecal flotation performed on one of the inpatient calves revealed the presence of cryptosporidia oocysts. Upon testing of additional inpatient calves, 6/6 (100 percent) were positive for *Cryptosporidium*. Among 20 calves tested which remained on the farm, 17 (85 percent) were positive. Other potential enteric pathogens identified in calves from this farm included

Campylobacter, *E. coli*, bovine coronavirus, and bovine rotavirus.

Results

Diarrhea occurring between March 16 and April 26, 1987 was reported by 26 of 112 questionnaire respondents (Table 1). With the exception of one unconfirmed illness, all cases were clustered in the three-week period between April 6 and April 26, 1987. In order to attempt to exclude short-lived illness due to viral and bacterial enteric pathogens and dietary upset, a case definition of diarrheal illness lasting at least three days was adopted. Nine respondents (7.4 percent) met this criterion and were defined as cases in subsequent analyses. Cryptosporidiosis was confirmed by identifying oocysts in stool specimens from four persons among six who reported diarrhea. Conversely, cryptosporidia were not detected in any of nine other individuals without a history of recent diarrhea.

Fourth year students had more frequent direct contact with diarrheic calves, adult cattle, and other animals than third year students during the outbreak. Three of the confirmed cases were fourth year students who had responsibility for therapy of the diarrheic calves in the isolation unit between April 1 and the date of diagnosis. The fourth was a female hospital employee whose spouse was a student. She denied contact with calves in the isolation unit. However, her husband had contact with the calves during the weeks of April 6 and 13 and she had washed his fecally contaminated clothing. She became ill during the week of April 13, complaining of a mucoid and watery stool, abdominal cramps, fever, nausea, vomiting, and flatulence.

A watery stool was reported by all patients. Abdominal cramping, flatulence, and headache were predominant features of the clinical disorder. The symptoms reported by persons with parasitologically confirmed cryptosporidiosis were generally similar to those reported by the unconfirmed cases.* The mean duration of illness in confirmed cases was seven days; the illness lasted over two weeks in one person.

The association between personal and occupational risk factors and the occurrence of gastrointestinal illness during the outbreak was examined.* The reference group comprised all fourth year student and staff respondents without a history of gastrointestinal illness (N = 52). Odds ratios of 13.2 and 11.8 were found for contact with a calf with diarrhea and having taken a calf's temperature, while intubating a calf for anesthesia carried no excess risk. The exact confidence intervals around these risk estimates were wide due to the small number of persons affected but did not include one. Contact with dogs, cats, or foals with diarrhea did not increase risk.

No association was found between human gastrointestinal illness during the outbreak and having a child in a day care center, or consumption of untreated surface water. The community is served by a municipal water system which uses complete conventional treatment consisting of chlorination, alum and polyelectrolyte coagulation and flocculation and rapid sand filtration through multimedia filters. Cases were not more likely than members of the comparison group to have had another illness, a history of frequent diarrhea or blood transfusion, or to have taken oral antibiotics during the previous month. A high proportion of both affected and unaffected students claimed to be under physical or psychological stress.

*Complete data available on request to authors.

TABLE 1—Frequency of Symptoms, Duration of Illness and Isolation of *Cryptosporidium* during Outbreak of Gastrointestinal Illness in a Veterinary Teaching Hospital, March 16 to April 26, 1987

Confirmed Cases	3	0	1	4

Discussion

The outbreak of cryptosporidiosis reported here reemphasizes the importance of this organism as a cause of gastrointestinal illness in previously healthy, immunocompetent persons.[6–8,15,16,21,22] Travelers, residents of day care centers, homosexual males, and children in developing countries constitute important risk groups for this cosmopolitan parasite.[23]

In the current outbreak, calves served as the source of human infection. This occurred despite the facts that veterinary students have frequent contact with diarrheic patients of many species, and that *Cryptosporidium* is reported to display little, if any, host specificity.[4] However, it is not clear if *Cryptosporidium* oocysts from animals other than cattle are infectious for humans. Previous reports of cryptosporidiosis in veterinary medical students have also involved contact with calves. In one, a student who provided supportive care of two calves with cryptosporidiosis became ill,[12] and in another, five students caring for experimentally infected newborn calves were affected.[13] In a recent report,[14] *Cryptosporidium* was detected in 10 of 20 students who had contact with 1-to-3-day-old calves in a student laboratory. The incubation period ranged from five to 14 days after exposure and the diarrhea lasted 30 hours to 16 days. Two infected students had only nausea or headache, suggesting that unrecognized infections may occur.

Reports of cryptosporidiosis in research workers[11,24] and animal handlers[8,24] with direct contact with feces from experimentally and naturally infected calves add to the evidence that the young calf is an important source of human infection. The reason for the consistent role of the calf as a source of cryptosporidiosis for humans is not clear, but may be related to the high prevalence of infection among calves,[25] and shedding of large numbers of oocysts for prolonged periods.[26] The preeminence of diarrheic calves as a source of transmission for zoonotic cryptosporidiosis dictates the necessity for exposed persons to adopt stringent hygienic precautions including protective clothing when working in an environment potentially contaminated with *Cryptosporidium*.

Fomites appear to constitute a hazard for the indirect transmission of *Cryptosporidium*. In the current outbreak, one confirmed human case had contact with clothing soiled with fecal material from infected calves as the likely source of infection. The oocysts of *Cryptosporidium* are resistant to desiccation and several disinfectants[27] and are thus likely to persist in the environment. Evidence that waterborne transmission occurs supports this hypothesis.[15,16]

The outbreak began approximately two weeks after the first calves were admitted, but the status of shedding of *Cryptosporidium* by specific animals was not determined until after the onset of the epidemic in humans. Instituting hygienic measures and awareness of the existence of an epidemic of gastrointestinal illness among students with contact with calves may have contributed to the cessation of clinical cases after the week of April 20, despite the fact that calves continued to be admitted to the hospital from the farm in question.

Public Health Service Implementation Plan for Responding to Nursing Shortage

The US Public Health Service has developed an implementation plan in response to the recommendations of the Secretary's Commission on Nursing, according to O. Marie Henry, RN, DrPH, PHS Chief Nurse Officer. Reporting recently to the Advisory Council on Nurses Education of the Health Resources and Services Administration, in Rockville, MD, Dr. Henry indicated that the plan is intended to coordinate activities and resources among PHS agencies and establish a focus within the US Department of Health and Human Services for responding to the nursing shortage.

In general, the plan continues current activities in such areas as research, financial assistance, and program development, within available resources, and also establishes new initiatives. The plan is organized around nine major objectives in the general categories of resource development, maintenance, and utilization, Dr. Henry said.

Copies of the 16-page "Public Health Service Implementation Plan for the Secretary's Commission on Nursing Final Report" are available from the Office of the USPHS Chief Nurse Officer, Room 14A-40, 5600 Fishers Lane, Rockville, MD 20857. Tel: (301) 443-0577.

Polymedicine Use among Community Resident Older Women: How Much of a Problem?

DORIS A. CADIGAN, PHD, JAY MAGAZINER, PHD, MSHYG, AND DONALD O. FEDDER, DRPH

Abstract: In a community-based study of older women describing the prevalence of specific medication combinations, the risk of deleterious consequence from polymedicine was concentrated in a minority of older women. There were few prevalent medication combinations, and many of the more common combinations were unavoidable. These results suggest that broad, community-based drug education programs may be less effective than those targeting medical providers and multi-drug users. (*Am J Public Health* 1989; 79:1537–1540.)

Introduction

As a group, the elderly suffer a larger burden of illness than younger adults, and consume disproportionately more medication;[1–3] community-based surveys report that about 70 percent of those over 65 years old take at least one medication.[4,5] Estimates of the average number of drugs taken at any one time varies considerably, from about 1.5 drugs to more than four drugs, depending on the age distribution of the sample, and whether those reporting no drug use were included in the average.[4,5] Moreover, age-related physiologic changes may increase the likelihood of adverse drug effects. Hence, older persons are thought to be at increased risk for the deleterious consequences of "polymedicine."[6,7] The size of this risk depends on the prevalence of specific medication combinations, yet little is known about the prevalence of specific medication combinations in the older community population, and none of the available information is specific to women. Women typically use more drugs than their male counterparts, although this association wanes somewhat with age.[8] However, women may be more susceptible than men to adverse drug reactions as they age because they experience larger declines in lean body mass.[9,10]

The purpose of this paper is to describe the prevalence of specific medication combinations in a community resident population of older White women.

Methods

Sampling Design

Study participants included 807 White women aged 65 and older living in a stable, relatively homogeneous urban community in a 20 census tract area in Northeast Baltimore. During 1984, a random sample of 6,540 addresses was enumerated from this community. The enumeration effort had a 95 percent response rate and yielded 1,203 homes occupied by at least one woman over age 65. If a household contained more than one woman over age 65, one was randomly selected to participate. Of the 1,203 eligible subjects, 807 (68 percent) agreed to participate. Details of this survey are available elsewhere.[11]

Prescription Drug Use

We asked respondents if they had taken any prescription medications during the past month and examined the original containers for all medications reported. Name, date of prescription, dose, and reason for taking each medication (using the information on the medication label) were recorded. Bottles were available for 91.6 percent of all prescriptions. Respondents provided information on other cases and, when necessary, dispensing pharmacies were contacted for clarification. Each drug was assigned the appropriate therapeutic drug code, using the American Medical Association's drug classification system.[12] The therapeutic codes were condensed into 10 drug categories. A number of drug categories with very low prevalence in this community dwelling population were omitted from the analysis. These included anti-malarial agents, anti-neoplastic agents, dermatologic compounds, and chelating agents.

Non-Prescription Drug Use

The interviewer also asked respondents if they had taken any non-prescription medications during the week prior to the interview. If the respondent answered affirmatively, the interviewer read the respondent a list of types of non-prescription drugs, including vitamins, laxatives, over-the-counter pain relievers, antacids, sleeping pills, and insulin, asking the respondent which ones she had taken.

Results

The 807 women in this sample report a mean age of 72.7 years, with a range of 65 to 99 years. Nearly 6 percent are over 85 years old. On average the respondents have completed 9.9 years of schooling, although 40 percent had

Antidiarrheal agents	1.5
Laxatives	0.4
Antiemetics	0.2
Miscellaneous	3.7

completed less than eight years of schooling and 10 percent had completed at least some college.

Prescription Drug Use

On average, the women in this sample report using 2.02 prescription drugs each, with a range of 0 to 11 drugs. The distribution of prescription medication use is presented in Table 1. Over one-fourth report using no prescription medications, while nearly 20 percent report using four or more prescription medications. Table 2 breaks down drug use by therapeutic category, and by class within category.

TABLE 3—Percent of Respondents Reporting Use of Each Category of Non-Prescription Drug

Drug Category	Percent Reporting Use
Vitamins	31.5
Laxatives	18.5
Pain relievers	31.0
Antacids	20.0
Sleeping pills	2.4
Insulin	1.2
Others	18.5

About 9 percent of all prescription medications had label instructions to use "as needed," including: 36 percent of the allergy/respiratory disorder drugs, 20 percent of the gastrointestinal agents, 27 percent of the central nervous system agents, and 21 percent of the drugs used for pain.

Use of Non-Prescription Drugs

The mean number of non-prescription drugs used in the week prior to the interview was 1.4 with a range of 0 to 7 (see Table 1). Twenty-three percent of the sample report taking no non-prescription drugs during the week prior to the interview, while 19 percent report taking three or more non-prescription drugs. Table 3 reports the percent of respondents reporting use of each category of non-prescription drug.

Analysis of Drug Combinations

To describe the potential extent of polymedicine in this sample, we ascertained the number of respondents reporting the use of each possible two-drug category combination by cross-tabulating all the drug category variables. The chi-square test with Yates' correction for 2×2 tables was applied to differences between observed and expected values. Tables 4 thru 6 report the results of this analysis. It is important to remember that the number of cases reported for any drug combination is bounded by the prevalence of the least frequently occurring drug in the combination.

Table 4 presents observed and expected frequencies for combinations of two prescription drugs. Of the 45 potential combinations, eight (18 per cent) occurred with significantly greater than expected frequency. It is noteworthy that about one in eight respondents (109/807) report taking the combination of cardiovascular renal agents and drugs for pain. This is not surprising since 44 percent of the women reported having high blood pressure, and 60 percent reported having arthritis, the two most common indications for use of cardiovascular renal agents and pain medications, respectively, in this sample.

Table 5 reports the observed and expected frequency of respondents reporting two-way combinations of one prescription drug and one non-prescription drug. Of the 60 combinations, five (about 8 percent) occurred with greater than expected frequency. Four combinations of cardiovascular-renal agents and non-prescription drugs have prevalence rates in this sample of over 10 percent. More than 25 percent of the sample (219/807) report using both cardiovascular renal agents and over-the-counter pain relievers. The combinations of cardiovascular renal agents with vitamins, laxatives, and antacids each occur in at least 10 percent of the sample.

Table 6 performs an analysis for two drug combinations of non-prescription drugs. Of the 15 potential combinations,

four (26 percent) occurred with greater than expected frequency. Two combinations of non-prescription drugs occur in more than 10 percent of the sample: vitamins and laxatives, and over-the-counter pain relievers and antacids. The latter was also reported with greater than expected frequency.

Discussion

This analysis indicates that there is a wide range of drug taking patterns among older women living in the community. While half the sample reported taking no or only one prescription medication, 20 percent reported using four or more prescription drugs. The use of non-prescription medications is equally varied. Hence, community dwelling older women are not homogeneous in their "risk" for the potentially deleterious effects of polymedicine.

An analysis of medication combinations demonstrates few prevalent combinations in this sample of community dwellers. In addition, many of the more prevalent combinations may be therapeutically unavoidable. For example, the combination of cardiovascular renal agents and pain relievers (prescription and non-prescription) occurs with high fre-

**$p < .01$

quency simply because many older women suffer from both hypertension/heart disease and arthritis. Other frequently observed combinations of medications result from the need to temper side effects—the co-occurrence of cardiovascular renal agents and hemeostatic/nutrient agents represents the need to add potassium supplements to diuretic therapy. Similarly, the frequent joint occurrence of over-the-counter pain relievers and antacids may reflect self-medication of the gastrointestinal side effects of aspirin.

Some of the more dangerous combinations fortunately occur with relatively low frequency. Some combinations of central nervous system agents and pain medications could be potentially dangerous. Overall, this combination occurs in about 4.5 percent of our subjects. In addition, six persons using a central nervous system agent and seven persons using a pain medication reported self-medicating with non-prescription sleeping pills.

Several caveats are in order. This sample derives from a community-based population of White women. While representative of a sizable portion of the older population, they can be expected to differ in important ways from other elderly. Treatment-based populations, both inpatient and outpatient, would overrepresent high medication users relative to this sample. Men and persons of other races may also differ from White women in their use of medications. Furthermore, these analyses use prevalence data. It is likely that our reports of drug use underestimate the incidence of drugs used for acute conditions.

Because relatively few older women report using many drugs, this analysis suggests that the risk of deleterious effects from polymedicine is not significant for the majority of community resident older women. A large minority, about 20 percent, are however, at substantial risk. Educational interventions directed toward providers which aim at encouraging appropriate prescribing and monitoring practices when treating older adults are already underway in many areas of the country. Given that this analysis suggests that the risk of deleterious effects of polymedicine is concentrated in a minority of older women, educational interventions should be directed at these community-dwelling, high medication users as well.

Factors Affecting Place of Death of Hospice and Non-Hospice Cancer Patients

CAROL MCMILLEN MOINPOUR, PHD, AND LINCOLN POLISSAR, PHD

Abstract: We identified factors associated with death at home for 28,828 hospice and non-hospice cancer patients in 13 counties of western Washington State. Hospice participation was found to be the variable most strongly associated with death at home. Admission to hospice appears to override the tendency for certain subgroups of patients, such as the extreme elderly and those diagnosed close to death, to die in an institutional setting. These findings are discussed with respect to the problem of selection bias. (*Am J Public Health* 1989; 79:1549–1551.)

Introduction

Death at home has been associated with availability of hospice programs[1,2] and whether or not the hospice is hospital-based or home care-based.[1,3–5] In addition, variables such as case mix, availability of caregiver support, and federal policies associated with the new prospective payment system and the Medicare hospice benefit are suspected of influencing length of stay in hospitals and hospice[4–14] and may affect place of death. A number of these variables were addressed in this analysis of factors associated with death at home for hospice and non-hospice cancer patients. Hospice participation was predicted to be a major determinant of death at home.

Methods

The study population included all 28,828 residents of 13 Washington State counties who died during 1980–85 with cancer as a primary cause of death, and whose diagnosis was made prior to death. Among this population, 6,762 were admitted to one of the hospices in the area. Cancer diagnosis information was obtained from the Fred Hutchinson Cancer Research Center Cancer Surveillance System and hospice data were obtained through the cooperation of 21 hospices.

We selected two types of independent variables: 1) previously established association with place of death and/or traditional adjustment or controlling variables (age at death, sex, race, marital status, rural/urban nature of county of residence, stage and site of cancer at diagnosis, presence of a contributory cause of death on the death certificate, time from diagnosis to death, and year of death); 2) policy-related variables (type of ownership of the hospital involved in continuing care of the patient, whether or not the hospital was affiliated with or had its own hospice program, whether or not the hospital was affiliated with or had its own home care program, and type of hospice program utilized).

The effect of independent variables on the relation between hospice participation and death at home was measured by a statistic derived from the relative risk.[15] In each stratum of a variable, the "scaled" relative risk was calculated as the stratum-specific relative risk for home death divided by the overall relative risk pooled across all strata. A variable that does not modify the hospice effect on place of death will have a scaled relative risk of 1.0 for all strata.

Logistic regression analyses were based on 26,500 patients with known values for all relevant variables. The dependent variable was coded as dying at home versus dying elsewhere. Independent variables in the logistic regression were modeled as dummy variables.[16]

Results

Hospice patients were 2.8 times as likely to die at home as non-hospice patients, the strongest association with place of death of any variable studied. Patients in hospice Home Health Based 1 and 2 programs were more likely to die at home than other hospice patients (Table 1). Inpatient hospice participants had a frequency of home death that was closer to the frequency for non-hospice than for hospice patients. The association of place of death with hospice participation yielded a p value $<.0005$ whether hospice was categorized as

*Reference Category for Dummy Variables

dichotomous (yes/no), as a five-category variable as in Table 1, or when limited to the four categories of hospice.

The variables that had both a statistically significant direct association with place of death (home versus other) and a significant interaction with hospice in affecting place of death are shown in Table 2. All interactions were significant with $p \leq .005$ except for year of death ($p = .02$).

The positive association of hospice with death at home was stronger for the very old (age 85+), for those not living in rural counties, for those diagnosed close to the time of death (the highest scaled relative risk), and for patients using for-profit and federal government hospitals instead of non-profit and local government hospitals. There was only a minor variation in the hospice association with place of death across categories of marital status and year of death.

A logistic regression model for place of death (home versus other) was fit including all variables from Table 2. The interactions of each of the variables with hospice participation (yes/no) were included in exploratory analyses. Initially 13 constructs (all levels of a variable or levels of interaction) were included. Constructs with a p-value of .05/13 = <.004 were retained in the model.

The final model is presented in Table 3. The main effects and interactions all had p-values below .0001. The pattern of main effect relative risks closely followed those in Table 2. Among the interactions, only that of hospice with age and with time from diagnosis to death remained significant. As in Table 2, the positive association of hospice with death at home modifies the relation between place of death and the two variables, age at death and time from diagnosis to death. Patients age 85 and older, and those diagnosed close to death were more likely to die at home than would be predicted by age at death, time from diagnosis to death, and hospice alone.

Discussion

Hospice participation is clearly the variable most strongly related to whether or not a cancer patient will die at home. It appears that once a patient is admitted to a hospice program, the strong philosophy supporting home deaths overrides the likelihood for patients with certain characteristics to die in hospitals or nursing homes.

Because this is an observational study, it is impossible to determine if the strong association of hospice with home death is causal or if it is due to the selection of hospice by people who prefer to die at home. It is likely that at least some of the association is a causal effect of hospice itself.

The relative risk of death at home for hospice patients varies across type of hospice program. These data are consistent with the results of the National Hospice Study[1,3] where patients cared for by hospices not controlling hospital

beds were almost twice as likely to die at home. It is still the case that, relative to non-hospice patients, hospice patients have a much greater likelihood of dying at home. Further, the effect of hospice also seems to be to counteract factors such as age that reduce the likelihood of death at home.

The Impact of Media Coverage of Nancy Reagan's Experience on Breast Cancer Screening

DOROTHY S. LANE, MD, MPH, ANTHONY P. POLEDNAK, PHD, AND MARY ANN BURG, MSW, PHD

Abstract: In surveys of random samples of women 50 years of age and older residing in two communities in Long Island, New York, both within-subject (cohort) and independent-sample comparisons were made before and after the media announcements of Nancy Reagan's breast cancer. Knowledge of lifetime risk of breast cancer increased significantly only in the cohort comparison, while self-perception of risk did not increase. Small proportions of women surveyed, however, reportedly were influenced to contact a health professional (6–8 percent) and to have their first mammogram (1.5–2 percent) which they attributed directly to Mrs. Reagan's experience with breast cancer. (*Am J Public Health* 1989; 79:1551–1552.)

Introduction

While the breast cancer experiences of public personalities could have an effect on awareness and use of cancer screening tests, no population-based studies have been published on the response to such media events. Black, *et al*,[1] found no evidence for improvement in stage distribution of breast lesions treated in two hospitals in New York City after the public announcements of breast cancer in the wives of the US President and Vice President in 1974. On October 15, 1987, Nancy Reagan's breast cancer was announced and in October–November newspapers and both local and network television reported that the cancer had been detected at an early stage by mammography. We examined the short-term effect of the news about Nancy Reagan's breast cancer experience on the breast cancer awareness and screening practices of women on Long Island.

Lane, MD, MPH, Associate Professor, Department of Community and Preventive Medicine, School of Medicine, State University of New York at Stony Brook, Stony Brook, NY 11794. Dr. Polednak is Associate Professor, and Dr. Burg is Instructor, both in the Department of Community and Preventive Medicine at SUNY. Additionally, Dr. Lane is Principal Investigator, Dr. Polednak is CoPrincipal Investigator, and Dr. Burg is Research Scientist, all with the Awareness of Breast Cancer Screening Project. This paper, submitted to the Journal February 6, 1989, was revised and accepted for publication May 17, 1989.

© 1989 American Journal of Public Health 0090-0036/89$1.50

Methods

As part of a community-based study,[2] a random sample of 254 female licensed drivers 50 years of age and older residing in two non-adjacent townships on Long Island were mailed a survey in September–October 1987 (time-1), with a $2 token prepayment. This survey included questions about past screening behavior (mammography, breast physicals, and self-examination), concerns about mammography, knowledge of breast cancer risk, and demographic characteristics. After three mailings (including certified mail) the final response rate to the time-1 survey was 68 percent (N = 183), excluding those who had died or moved out of the area. The 173 who had responded prior to the announcement of Mrs. Reagan's surgery in the media were sent a follow-up survey in November–December (time-2). The 142 women responding to both surveys comprise the cohort group. Surveys were also sent in November-December to an independent sample of women randomly selected from the same two Long Island communities (time-2), with a response rate of 71 percent (N = 205). To assess the changes in responses from time-1 to time-2, chi-square was used for the independent samples and a matched-pair or McNemar chi-square test was used for the cohort.

Results

There were no significant differences between these

groups of women in age, education, or income (Table 1). The follow-up surveys at time-2 directly asked women whether they had heard about Nancy Reagan's experience with breast cancer and to what extent their screening behavior had been influenced by that experience. Some 85–88 percent of the women surveyed at time-2 had been exposed to the news of her breast cancer in the month after the event through both newspapers and TV coverage, and the majority of women (57–62 percent) also heard about it on the radio. About 8 percent of the cohort respondents and 6 percent of the independent sample (time-2) respondents reportedly contacted a doctor or other health professional as a result of Mrs. Reagan's experience; none contacted either the American Cancer Society or a hospital.

In the period between the two surveys, 17 of the 142 women in the cohort had mammograms, three of whom had never had a mammogram previously. Among these 17 women, 12 said that their decision was not influenced "at all" by Nancy Reagan's experience, three were "somewhat" influenced, and only one was influenced "a great deal." The latter four included the three women (or 2.1 percent of the 142) who had their first mammogram in this period.

Among the independent sample time-2 respondents, 17 women had a mammogram in the October to December period; five of these women had never had a mammogram previously. Of these 17 women, three who said that their decision was influenced by Mrs. Reagan's experience had never had a mammogram previously (3 of 205 or 1.5 percent).

Changes in proportions of correct responses to knowledge questions were slight but in the direction of improved knowledge. In the cohort at time-2, the proportion of correct responses to the question regarding lifetime risk of breast cancer had increased significantly (Table 2) but there was no increase in the proportion of cohort respondents who considered it "very likely" or "somewhat likely" that they would get breast cancer.

TABLE 1—Selected Characteristics of Cohort and Independent Samples

Characteristics	Cohort (N = 142)	Independent Samples Time-1 (N = 183)	Independent Samples Time-2 (N = 205)
Mean Age (years)	62	63	63
Education Level Completed			
≤High school	63 (45.3)	82 (45.8)	99 (48.8)
1–3 years of college	37 (26.6)	47 (26.3)	57 (28.1)
College graduate+	39 (28.1)	50 (27.9)	47 (23.1)
Annual family income			
≤$15,000	27 (20.3)	39 (24.2)	45 (24.1)
$15,000+	106 (79.7)	122 (75.8)	142 (75.9)

TABLE 2—Percent Changes in Response from Time-1 to Time-2

Variables	Cohort	Independent Samples
Correct answer to what proportion of women will get breast cancer at some time in their lives	+9.2%[a] (p = .049)	+3.5% (p = .412)
Perceives self at risk for getting breast cancer	−5.6%[b] (p = .136)	−1.6% (p = .711)

NOTE: P values in the cohort sample are probabilities (two-tailed) obtained by using the normal approximation to the binomial for analysis of discordant pairs.[9]
[a]McNemar chi-square = 3.89, p < .05.
[b]McNemar chi-square = 2.23, p > .10.

Discussion

This study examined the population-level response to the media attention paid to a public figure's experience with breast cancer. Almost all women over the age of 50 had heard about Nancy Reagan's experience through the media and a very small proportion of the defined population sample was influenced in terms of a behavioral change—i.e., seeing a health professional or having their first mammogram. The slight increase in knowledge of risk was not accompanied by an increased sense of personal susceptibility to breast cancer.

Data from the 1987 Behavioral Risk Factor Surveillance System (BRFSS) analyzed by the Centers for Disease Control[3] showed an absolute increase of 12 percent in screening mammography use between the first two months of 1987 and the last two months of 1987 among women who had a medical checkup in that year. The CDC noted the temporal association with Mrs. Reagan's breast cancer but could not attribute the increase in mammography to this event because the effects of the media coverage of the Nancy Reagan news could not be distinguished from the media attention paid to other cancer control promotions in the same year.

According to the Health Belief Model, a media event can serve as a cue or a trigger for an individual to take a preventive health action but the effectiveness of the external cue depends on a complex host of variables including the perceived benefits of an action, the structural barriers to taking an action, as well as the intensity and duration of the cue.[4] On the basis of communication research, the rapid diminution of the effect of episodic information,[5–7] even if widely diffused (as with Mrs. Reagan's experience), may be overcome by community-based interventions[8] that maintain any changes in knowledge, attitudes, and behavior and that help in removing barriers to screening. The small increase in numbers of women contacting a health professional, and the direct attribution of the adoption of first-time use of mammography to the news of Nancy Reagan's breast cancer by a small number of women found in this study, may provide impetus for further work on the integration of such experiences with intervention programs to encourage preventive health behaviors.

Is Testicular Cancer Incidence in Blacks Increasing?

STEPHEN K. VAN DEN EEDEN, RN, MS, AND NOEL S. WEISS, MD, DRPH

Abstract: Using data collected by the Surveillance, Epidemiology and End Results Program (SEER) from 1973–84, we found no evidence of an increase in the incidence of testicular cancer in Blacks, in contrast to an increase of nearly 33 percent in Whites. (*Am J Public Health* 1989; 79:1553–1554.)

Introduction

In 1985, Sagalowsky and Admire,[1] on the basis of treating four testicular cancer cases in Blacks in the early 1980s compared to none in the previous seven years, hypothesized that the incidence rate of testicular cancer was increasing in Blacks during the 1970s and early 80s. Epidemiologic studies in the past have reported no increase in testicular cancer in Blacks but definite increases in Whites.[2–6] We sought to update earlier studies.

Methods

Data were obtained from the Surveillance, Epidemiology and End Results (SEER) Program of the National Cancer Institute.[7] There were 4,788 cases of testicular cancer in Whites and Blacks identified between January 1, 1973 and December 31, 1984 by the SEER registries, of which greater than 99 percent were histologically confirmed. Testicular tumors were classified into three broad histologic categories using the International Classification of Diseases for Oncology (ICD-O)[8]: seminoma (9060-9064), non-seminoma germ cell (9070-9073, 9080-9083 and 9100-9102) and all other tumors. Population estimates based on US Bureau of the Census estimates were provided by the SEER Program. All rates presented are standardized to the age distribution of the US population in 1980 and expressed per million men per year. Poisson regression was used to evaluate whether the linear slope of the incidence rates by year of diagnosis differed from zero.[9]

Results

Table 1 shows the incidence rates of testicular cancer by year, age, histology and race during 1973–84. In Black men, with a total of 103 cases, there was no evidence of any increase in rate during the interval, for the individual histological categories, for all categories combined, or by age. In contrast, during the same time period, the incidence of testicular cancer in White men increased nearly 33 percent, primarily in age groups below 50 years and in seminomas.

Discussion

In Blacks, no increase in the incidence of testicular cancer was apparent during 1973–84. Data on testicular cancer in US Blacks for earlier decades are limited, and it

remains uncertain whether there has been an increase over a longer time period. All of this contrasts to the clear steady rise of testicular cancer incidence in US White men, both during 1973–84 and earlier.

The explanation of this discrepancy in trends lies either in a difference in susceptibility to the agent(s) responsible for the increase seen in Whites and/or to a lower level of exposure to these agents. The similarity of the White:Black incidence ratio for testicular cancer in different populations supports the hypothesis that there are at least some racial differences in susceptibility. In South Africa's Cape district, the rate ratio was 3.3 (Whites compared to "coloured")[10] while the ratio in the US is around 4.5[4–6] Further, the incidence of testicular cancer in Blacks is very similar in different areas of the world.[11–15] However, the presence of such a difference in susceptibility between the races does not preclude the possibility that Whites have been increasingly exposed to a greater extent than Blacks in recent decades to some, as yet unidentified, exposure that predisposes to testicular cancer.

Self-Report and Medical Record Report Agreement of Selected Medical Conditions in the Elderly

TRUDY L. BUSH, PHD, MHS, SUSAN R. MILLER, MPH, ANNE L. GOLDEN, MSPH, AND WILLIAM E. HALE, MD

Abstract: This study assessed agreement between self- and medical record report of medical conditions in an elderly population. Medical charts of 120 participants in a screening program were abstracted, and the questionnaire report of eight major conditions was compared with the medical record. There was substantial or moderate agreement between self-report and medical record report for each condition, although strength of agreement varied by condition. Self-report by elderly individuals compares favorably with medical record report of medical conditions. (*Am J Public Health* 1989; 79:1554–1556.)

Introduction

Information on medical conditions is frequently gathered by questionnaire because a standardized medical examination would be impractical and expensive, but the accuracy of self-reported information is seldom assessed. This is of particular concern in elderly persons, who may be more likely to misreport information than younger individuals. The purpose of this study is to evaluate the agreement between self-report and medical record report of selected medical conditions in elderly individuals.

Methods

Population

Individuals in this study have participated for at least three years in the Florida Geriatric Research Program, a health-screening program located in Dunedin, Florida. This free program is open to all ambulatory residents of Dunedin over 65 years of age; over 45 percent of the age-eligible residents have been enrolled. The program began in July 1975 and screens 2,200 persons each year.

Participants are seen annually for a clinic visit, where they are given a brief medical examination and complete a detailed questionnaire ascertaining previous and present illnesses. Detailed descriptions of this population have been published.[1]

For this analysis, a 10 percent random sample of participants who had their annual clinic visit between July 1, 1985 and December 31, 1985 was selected. These individuals

were sent a letter requesting permission to review their medical records.

Medical Record Review

Mease Health Care, Inc. (MHC), a private hospital with a large outpatient clinic, serves the Dunedin community. All medical records (both inpatient and outpatient) of MHC were requested for sampled individuals. One of us (TLB) then reviewed each medical record and noted the occurrence and date of first diagnosis of the following conditions: angina pectoris, cancer, cataract, diabetes, fracture, hypertension, myocardial infarction, and stroke. Any non-definitive diagnosis (i.e., possible stroke) was also noted.

Questionnaire Responses

The wording of the questions used is presented in Table 1. Except for cataracts, possible responses to each question are: Yes, No, or Unknown. Possible responses to the question on cataracts are: One Eye, Both Eyes, or None.

Analysis

The medical record diagnosis for each condition (yes or no) was compared to the self-report (yes or no) obtained by questionnaires administered at all previous program visits. Medical record diagnoses after the date of completion of the questionnaires were ignored. We did not assume the medical record was more correct than the self-report. The percent agreement between the two reports, the kappa statistic, and z-scores for kappa were calculated.[2]

Results

In this study, 120 of the 122 randomly selected individuals consented to a medical chart review. The two participants not providing consent had died between their clinic visit and the request for permission to review. Of these 120 persons, 115 had received care at MHC and theoretically had charts available for evaluation; charts were located and reviewed for 68 women and 39 men (total = 107). At their first visit, participants ranged in age from 65 to 90 years ($\bar{x}$ = 71 years). Of the 170 medical diagnoses noted in the medical records, 62 percent were diagnosed after 1975 and 38 percent prior to 1975.

The proportion with a positive response on medical record or self-report, the percent agreement between self-report and medical record report, and kappa are presented (Table 2). Angina pectoris, cataract, fracture, hypertension, and myocardial infarction were somewhat more likely to be noted in the self-report, whereas cancer and stroke were slightly more often noted in the medical record.

TABLE 1—Questionnaire Items Used in Self-Report of Selected Medical Conditions in the Elderly

Condition	Wording of Question
Angina	Have you ever been told by a doctor that you have angina?
Cancer	Have you ever been told that you had cancer and this was confirmed?
Cataract	Have you been told of cataracts in the *following*?
Diabetes	Do you have diabetes mellitus?
Fracture	Have you had any broken bones within the last five years?
Hypertension	Have you ever been told that you have hypertension or high blood pressure?
Myocardial Infarction	Have you had a heart attack, thrombosis, coronary, or myocardial infarction?
Stroke	Have you ever had a stroke?

TABLE 2—Percent Positive Responses by Self-Report and Medical Record Report, Percent Agreement Between Self-Report Medical Record Report and Kappa: Selected Conditions

Condition	N	Positive Report by % Self	% Medical Record	% Agreement	Kappa
Angina	103*	26.2	15.5	85	.57
Cancer (Any)	107	24.3	31.8	89	.72
Cataracts	105*	50.5	34.3	76	.53
Diabetes	107	16.8	16.8	98	.93
Fracture	103*	22.3	13.6	91	.71
Hypertension	107	46.7	32.7	86	.71
Myocardial infarction	107	12.1	8.4	94	.70
Stroke	107	5.6	7.5	98	.85

*Four persons were excluded from these analyses either because a non-definitive diagnosis was listed in the medical chart or unknown was checked on the questionnaire.

The percent agreement between self-report and medical record report ranged from 76 percent for cataract to 98 percent for stroke and diabetes. The overall agreement was 89 percent. There were no differences in agreement by sex or recency of condition. All kappa values had p-values <.001.

Discussion

Public health researchers are concerned about the validity of self-reported information.[3,4] In this study, agreement is high between the self-report and medical record report of common medical conditions. Kappa scores for six of the eight conditions are >0.6, indicating substantial agreement.[5] Kappa values between .40 to .60, seen for the remaining two conditions, are evidence of moderate agreement.[5]

There are several limitations to this study. First, participants were not a representative sample, but volunteers who came to a screening program and may be different from non-participants in their interest and knowledge of health-related matters. Over 45 percent of the age-eligible residents of Dunedin were enrolled, however, and the self-reported prevalence of these conditions is very similar to the prevalence reported in three other community studies of elderly persons.[6]

A second limitation is that the respondents had all participated in this screening program, and participation may have affected their knowledge about their health status. However, elderly individuals in general are more knowledgeable about their health than are younger persons[7]; 80 percent of older Americans visit physicians at least once a year, with the average physician visits = 4.8/year.[8] Whether and to what degree participation in this program would enhance participants' knowledge over and above what they ascertain from physician visits is unknown.

An additional limitation is that the medical records were from the one major hospital/clinic in Dunedin. Participants may have had conditions diagnosed in other medical locations and this information may not be in the reviewed chart. The effect of this type of error would be to lower the agreement between the two sources.

Although overall agreement between self-report and medical record report is good to excellent, there is variability in the percent agreement among the medical conditions. This variability in prevalence by ascertainment source has been reported previously in younger persons,[4,9–13] and probably

results from errors at each source. Self-reported information can be wrong for numerous reasons including a misunderstanding of the diagnosis presented, or the forgetfulness of the individual reporting. Likewise, medical records are not necessarily an accurate source of information.[14–21] Serious non-reporting or misreporting of diagnoses in medical charts has been found in several studies.[16–18,20]

Given the potential sources of error with both methods of ascertaining information, it is impossible to know which assessment comes closest to truth. For most important conditions this is probably not an issue, since self-report is significantly correlated with medical record report.

ACKNOWLEDGMENTS

Geographic Variation in the Occurrence of Hip Fractures among the Elderly White US Population

W. Edward Bacon, PhD, MPH, Gordon S. Smith, MBChB, MPH, and Susan P. Baker, MPH

Abstract: Geographic variations in hip fracture rates across the nine US Census Divisions were examined using data for elderly Whites from the 1979–85 National Hospital Discharge Survey. Rates varied considerably and were highest in the West North Central Division where rates for females were 50 percent higher than the US rate. Reasons for the geographic variations in hip fracture rates are unknown but do not appear to be closely related to latitude or fall-related deaths. (*Am J Public Health* 1989; 79:1556–1558.)

Introduction

Fractures of the hip result in over 250,000 hospital admissions each year and, in the elderly, represent 25 percent of all injury admissions.[1] A number of risk factors have been identified for osteoporotic hip fractures including increasing age, White race, and female sex.[2–5] Incidence rates for hip fracture also vary considerably from one country to another and a high rate has been reported for the United States in comparison with other countries.[2,3,6] This study explores geographic variations in hip fractures within the US using data from the National Hospital Discharge Survey (NHDS).

Methods

The NHDS collects data annually on a representative sample of discharges from nonfederal short-stay hospitals in the US.[1] The data set for this study consisted of all sample discharges from 1979 to 1985 among Whites, age 65 years or older in whom hip fracture (ICD-9-CM codes 820.0 to 820.9) was one of the discharge diagnoses. Blacks and other races were excluded from the analysis because of the small number of sample cases. Cases for which race was not stated were considered White based on previous demographic analysis.[4] All discharges whose hospitalization involved late effects of hip fracture (ICD-9-CM code 905.3) or complications of a previous fracture (ICD-9-CM code 733.8) or who were transferred to another short-stay hospital were excluded to minimize multiple counting of the same fracture. The final sample contained 6,701 discharges.

Geographic comparisons were limited to the nine US Census Divisions[7] because of the design characteristics of the

Address reprint requests to W. Edward Bacon, PhD, MPH, Division of Health Care Statistics, National Center for Health Statistics, 3700 East-West Highway, Room 2-63, Hyattsville, MD 20782. Dr. Smith and Ms. Baker are with the Injury Prevention Center, Johns Hopkins School of Hygiene and Public Health. This paper, submitted to the Journal October 13, 1988, was revised and accepted for publication April 18, 1989.

NHDS.[8] Based on the sample, the projected total numbers of hip fracture patients discharged each year were computed by hospital Census Division using the NHDS weighting factors.[8] Age/sex-specific rates were derived from the mean annual number of discharges and Census estimates of the White civilian population as of July 1, 1982 for male and female age groups 65–74 years, 75–84 years, and 85 years and older. Age/sex-adjusted rates were based on the above age/sex-specific rates and the 1982 US White population as the standard. Standard errors were based on the 1982 NHDS,[9] were adjusted to account for aggregating multiple years of data,[8] and assumed the standard population was not subject to sampling error.

Results

Age/sex-adjusted hip fracture rates per 1,000 population and 95% confidence intervals are shown for the nine US Census Divisions and for the US in Figure 1. Comparisons of all pairs of rates among the nine Census Divisions using the Bonferroni Inequality[10] (comparison wise p = .0014) indicated the rate in the West North Central Division was significantly higher than the rates in all other Divisions except the Mountain and Pacific Divisions.

Age/sex-specific rates (Table 1) were generally higher in the West North Central Division for each age and for both sexes compared to other Divisions. For females, the West North Central rates were at least 45 percent higher than the corresponding US rates in each of the three age groups. Only for males age 75–84 were discharge rates higher in other Divisions (Mountain and Pacific). The highest rates also occurred in the West North Central Division in each of the seven years from 1979 to 1985, the time period over which the data were aggregated.

Discussion

Although hip fractures typically result in hospitalization, hospital discharges cannot be assumed to equal hip fracture incidence—particularly because of multiple counting of cases due to transfers from one hospital to another, and readmissions for additional treatment of old fractures.[11–13] To minimize this potential bias, all transfers to another short-stay hospital and all hip fracture cases with a secondary diagnosis of malunion or late effects were excluded. The data base does contain refracture cases which may represent as many as 15 percent of the discharges.[5,14–16] However, there is no reason to believe that refracture rates would vary greatly by geographic area and, as

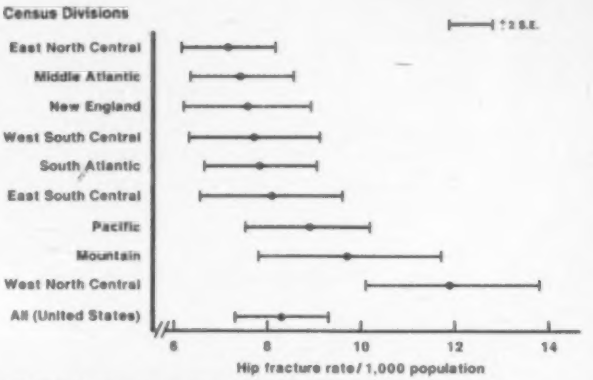

FIGURE 1—Mean Annual Hospital Discharge Rates for Hip Fractures per 1,000 White, Elderly, Civilian Population by Census Division
New England: ME, NH, VT, MA, RI, CT

West South Central: AR, OK, LA, TX
Mountain: MY, WY, ID, CO, UT, NV, NM, AZ
Pacific: WA, OR, CA, AK, HI

new events, should be included in estimates of fracture incidence.

Factors such as listing old hip fractures as secondary diagnoses, admitting patients with old hip fractures for arthroplasty, and admitting patients residing outside the Census Division of the hospitals could vary by Census Division and thus are potential sources of bias. Analyses of these variables showed little geographic variation, however.

To corroborate the findings using a different data source, discharge data from a 20 percent sample of all inpatient bills were obtained from the 1985 Health Care Financing Administration (HCFA) MEDPAR file. Hip fracture rates for aged Medicare beneficiaries were also highest in the West North Central Division compared to other Divisions.

This study indicates that discharge rates for hip fracture in elderly Whites is higher in the West North Central region of the US than in other Census Divisions for reasons which are not clear. Several factors have been associated with an increased risk of osteoporotic fractures[2,3,5,16–19] but many, such as diet and exercise, would seem less prevalent in the farm states of this

region. Sunlight exposure is unlikely to be a major factor because rates are dramatically different among regions at similar latitudes (e.g., West North Central and East North Central Divisions). Further, a relationship of geographic variation in hip fracture rates to reported mortality from falls is not evident despite the fact that falls account for most hip fractures in the elderly.[20,21] All seven States in the West North Central Division have above-average death rates from falls in elderly Whites, and Iowa and Minnesota are among the 10 States with the highest rates.[22] However, New England has a high death rate for falls and a relatively low discharge rate for hip fractures. (If case-fatality rates for hip fracture are relatively constant, differences between discharge and mortality rates may reflect geographic variations in the reporting of falls as a cause of death on the death certificate.[23,24]) It is interesting that a relatively high proportion of residents in the West North Central region originate from Scandinavian countries[25] where the incidence of hip fractures is also high.[2,3,6] Further investigation of the factors responsible for the geographic variations observed may lead to new insights into the causes of hip fractures.

ACKNOWLEDGMENTS

The authors express their appreciation to Charles Helbing, Health Care Financing Administration, for providing us with Medicare program data from the MEDPAR inpatient person record file.

The results of this study were presented during an informal work session by the first author at the International Collaborative Effort on Aging held in Bethesda, Maryland on December 7–9, 1988.

Lead Exposure and Radiator Repair Work

DANIEL H. LUSSENHOP, MD, MPH, DAVID L. PARKER, MD, MPH, ANITA BARKLIND, MS, AND CHUCK MCJILTON, PHD

Abstract: In 1986, the ambient air for lead in radiator repair shops in the Minneapolis-St. Paul metropolitan area exceeded the Occupational Safety and Health Administration (OSHA) action level in nine of 12 shops sampled by Minnesota OSHA. We therefore sought to determine the prevalence of lead exposure/toxicity in this industry. Thirty-five radiator shops were identified, 30 were visited, and 53 workers were studied. The mean blood lead level was 1.53 (range 0.24–2.80). Seventeen individuals had blood lead levels ≥1.93 μmol/L (40 μg/dl). The mean zinc protoporphyrin level (ZPP) was 0.55 μmol/L (range 0.16–1.43). No single worksite or personal characteristic was a strong determinant of either blood lead or ZPP level. (*Am J Public Health* 1989; 79:1558–1560.)

Introduction

Workers in the automotive radiator repair industry are known to be at risk for exposure to inorganic lead from lead-based solder used in the repair of radiators.[1–8] Lead fumes arise from molten lead and lead oxide dusts result from grinding and wire brushing radiator joints. These operations are done less frequently now than in the past, largely due to the recognition of the health hazards they cause.[9] It is claimed that more efficient ventilation, and self-contained breathing apparatus for radiator cleaning have reduced much of the lead exposure.

Results of recent studies in the upper Midwest area of the United States revealed that radiator repair shops may have elevated air lead levels, and that repair workers may have

elevated blood lead levels, occasionally higher than 2.90 μmol/L (60 μg/dl).[2–5] An auto radiator trade journal performed a questionnaire survey in 1977,[6] in which 100 radiator workers voluntarily reported information including recent blood lead levels, work history and habits, shop characteristics, and personal health history. Blood lead levels ranged from 0.63 to 5.45 μmol/L. Departments of health in some states have attempted to study auto radiator repair shops in a systematic way, with varying degrees of success. Although no publications in the scientific literature resulted, blood lead levels in excess of 4.34 μmol/L were found in some workers (personal communication, Michigan and Wisconsin Departments of Health).

In the summer of 1986, Minnesota OSHA (Occupational Safety and Health Administration) sampled the ambient air for lead in nine radiator repair shops in the Minneapolis-St. Paul area. Air in two of these shops exceeded three times the OSHA standard for ambient lead, and three others exceeded the OSHA action level. The standard Permissible Exposure Limit for lead for a 40-hour work week is 0.05 mg/m^3. This information, together with the results of previous studies, led us to question the degree of lead exposure and toxicity in auto radiator repair workers in the Minneapolis-St. Paul area. We sought to determine the prevalence of lead exposure and toxicity in these workers and characteristics associated with elevated lead levels.

Methods

All automobile radiator repair shops within Minneapolis-St. Paul and their closest suburbs were identified using the Minneapolis-St. Paul yellow page directories. The owners were asked to permit a visit by a study investigator to administer a questionnaire to shop employees and obtain blood samples for lead and zinc protoprophyrin levels (ZPP).

During November 1986, a visit was made to each shop whose owner consented to participate in the study. The shop owner or manager was interviewed to obtain information on shop size, number of cars serviced, and workplace conditions. Permission was then obtained to interview all radiator repair workers present at that time. Each radiator repair worker was then asked demographic questions, recent work history, workplace and general health practices, directed health history, and whether the worker had children under the age of six living in the home. If such children were present, permission was requested to screen them for lead.

Blood lead determinations were done by the anodic stripping voltametry method.[7] ZPP determinations were done at the University of Minnesota using a hematofluorometer.[8] Individual workers were each informed of their blood lead levels by letter, with an accompanying explanation of the results. Shop owners were also furnished with this information if the employee had given written consent to do so.

Later, the shops were visited by an individual hygienist who took area samples for three to six hours using high flow air sampling pumps.[10] Personal breathing zone air samples were also done by attaching the filter cassette of the sampler to the shirt lapel of the participating worker. Analyses of samples were done by atomic absorption.[11] Each shop owner was informed of air measurements with an explanation of the level of lead in the air.

Statistical analyses were done using the Statistical Package for the Social Sciences (SPSS). Shop data for individuals from the same shops were identical, but were treated independently for purposes of analysis because the shops were small, with most having one or two workers, and analysis of covariance showed neither shop size nor number of radiators repaired per year in a specific shop to be significant covariates.

Regression analyses were done with blood lead and ZPP as dependent variables, and several of the items from the shop and individual questionnaires, and area and personal air lead samples, as independent variables. All specified variables were included in the regression model.[12,13] A chi square statistic was computed for categorical variables. In the latter analyses, blood lead (1.93 and ≥1.93 μmol/L) and ZPP (<0.89 and ≥0.89 μmol/L) were treated as categorical variables with two levels each.

Results

Shop Characteristics

Thirty-five radiator shops were identified in the metropolitan area. Of these, 30 were visited, making the shop participation rate 85.7 percent. One shop was not visited because, although the shop owner was cooperative, the radiator repair workers themselves refused to participate. The owners of the other four shops refused to participate.

Shops were small, usually 300 to 600 square feet, and there was generally no interior finish (Table 1). The amount of business varied greatly between shops. While use of specific work site ventilation was often reported by shop owners and the individual workers, only a few had local ventilation and most ventilation systems were not in operation. All but one shop supplied tools for their employees, all had salaried employees, and none had working showers. All shops used solder comprised of 60 percent lead and 40 percent tin.

Area and personal air sampling for lead levels were done in 24 of the 30 shops. Six shops refused to have air monitoring. Personal air lead samples were obtained from individuals in 16 of the 24 shops. Workers refused to wear a pump in eight shops. The mean area lead value was 0.040 mg/m^3 with a range of 0 to 0.281 mg/m^3 (SD = .060). The mean personal air lead value was 0.113 mg/m^3 with a range of 0 to 0.590 mg/m^3 (SD = .020).

Worker Characteristics

A total of 57 radiator repair workers were identified. Of these, four refused to participate in the study, but at least one radiator repair worker was evaluated in each participating shop. Of these workers, the mean age was 37.1 years (SD = 2.8 years), mean education was 11.9 years (SD = 2.8 years), and mean work experience was 14.3 years (SD = 11.2 years). Table 2 details other worker characteristics. Most of the workers identified job duties other than radiator repair that they normally performed, but none involved significant lead exposure. No worker reported ever having been treated for lead toxicity, although five out of 53 reported having had elevated blood lead levels in the past.

TABLE 1—Characteristics of Thirty Radiator Repair Shops

Variables	Mean	Standard Deviation	Range
Age of Shop (years)	17.0	15.5	<1–50
Number of Employees	3.6	2.7	1–10
Number of Radiator Repair Workers	1.9	1.5	1–8
Number of Cars/Trucks Repaired Per Week	43.2	40.8	0–200
Number of Radiators Repaired Per Week	35.5	38.2	1–200
Number of Radiators Repaired Per Year	1281.7	932.2	50–3500

TABLE 2—Self-reported Characteristics of Radiator Repair Workers

Characteristics	Category	Number (%)
Respiratory Protection	Never	41 (77.4)
	≤25% of time	8 (15.1)
	>25% of time	4 (7.5)
Gloves Used	Never	7 (13.2)
	≤50% of time	8 (15.1)
	>50% of time	38 (71.7)
Eat Lunch at Work Stations	Never	48 (90.6)
	≤25% of time	1 (1.9)
	>25% of time	4 (7.5)
Smoke Cigarettes	Yes	32 (60.4)
	No	21 (39.6)

Twelve individuals reported having children under the age of six living at home. Sixteen children were later screened for blood lead and, with one exception, levels were below 0.724 μmol/L, and a mean of 0.45 μmol/L (range = 0.24 to 1.06 μmol/L). This did not correlate well with workers' blood leads, and no further analyses were done.

As seen in Tables 3 and 4, there was a wide range of blood lead levels among the workers. Symptoms associated with lead toxicity included frequent headaches, abdominal cramps, constipation, and muscle aches. None of these symptoms was common in the workers but none was significantly associated with either blood lead or ZPP level.

In bivariate analyses, two variables were associated with increased blood lead levels: number of radiators repaired in the past month (0/8 vs 17/44; 95% CI = 0.09, 0.69)*; and shop age (4/24 vs 13/29; 95% CI = 0.21, 0.35). Years of work experience was the only variable found to be related to ZPP level (3/20 vs 18/33; 95% CI = 0.12, 0.67). Confidence intervals are for the difference in the proportion of workers with elevated blood lead in the high-risk (exposure) group compared to the proportion of workers with increased blood lead in the low-risk (exposure) group.

Multiple regression was used to examine the simultaneous effects of worksite and personal factors. Four variables were entered into the regression for blood lead level; years of work experience ($\hat{B}$ = 0.25, SE 0.15), worker time spent in radiator repair during the last month (2.00, SE 1.43) and last year (0.03, SE 0.18), and shop age (5.97, SE 744), the total r^2 was 0.25. Work experience was the only variable that contributed to the ZPP level (0.89, SE 0.18, r^2 = 0.34).

Discussion

About one-third of the workers had lead levels that were elevated by OSHA standards.[14] Minnesota radiator repair workers had lead levels that were similar to those found in recent studies in this country.[1–5,15] These levels are considerably less than those routinely seen in the high-risk occupations such as lead smelting, storage battery manufacturing, or metal foundries were levels occasionally exceed 4.83 μmol/L.[16] However, the blood lead level[3] found in radiator workers exceeds those in the general population, where mean lead levels in adult males is 0.63–0.72 μmol/L.[16] Auto radiator repair workers appear to be at a risk of mild to moderate elevations in blood lead levels.

No single worker characteristic or practice was a good predictor of elevated blood lead. Only two shop characteristics—volume of radiator repair done and shop age—were associated with elevated blood lead levels. Environmental data did not correlate well with blood lead levels. This may have occurred because of the variability of the volume of work in each shop from day to day as well as our having been invited into shops on "less busy days." The data presented here confirm earlier studies of this industry. There is need for worker education, safer worker practices, and better shop design and ventilation in the radiator repair industry.

*One worker had not done radiator repair during most of the month prior to the study.

TABLE 3—Number of Individuals with Blood Lead Levels by Approximate Quartiles*

Acute Illnesses among Los Angeles County Lifeguards According to Worksite Exposures

CONSTANCE S. B. SULLIVAN, DRPH, AND MARY E. BARRON, MPH

Abstract: Due to public concern regarding the potential adverse health effects of exposure to Santa Monica Bay waters, a case-control study of acute illnesses among Los Angeles County lifeguards was conducted. Workers' compensation claimants (N = 112) were matched to healthy lifeguards working in the same year and having the same job classification. Conditional logistic regression showed that the southernmost worksites of the bay were associated with all acute illnesses (OR = 14.4, 95% CI = 4.7, 44.8) and with ear infections (OR = 12.5, 95% CI = 2.9, 53.4). (*Am J Public Health* 1989; 79:1561–1563.)

Introduction

The quality of water in Santa Monica Bay of Los Angeles County, California has been the subject of debate because of the dumping of industrial waste and sewage into the bay and untreated discharges into the surf zone from numerous storm drains along the shore.

Most studies of water quality and adverse health outcomes have established a direct correlation between pathogen levels in the water and disease incidence in swimmers,[1–5] while two found no relationship.[6,7] Cabelli and coworkers found a dose-response relation between swimming-associated gastrointestinal symptoms and water quality (as measured by enterococcus concentrations) at a group of New York City beaches.[1] In a study of five Ontario lakes conducted by Seyfried and Cook,[4] otitis externa was related to water levels of *Pseudomonas aeruginosa* and to the frequency of swimming.

To assess the potential adverse health effects of exposure to the waters of Santa Monica Bay, we studied work-related acute illnesses in an occupationally exposed population—Los Angeles County lifeguards. This is the first study of a defined population exposed to these waters.

Methods

We used a case-control design, with cases defined as all episodes in which lifeguards made a compensable claim for a work-related, acute illness in the years 1980 through 1986. Lifeguards with repeated acute illness claims in a single year were included only once. A healthy lifeguard was chosen as a control for each case. The control lifeguard worked the same year that the case was ill, had no acute illness claim in that year, and worked in the same job class (i.e., temporary assignment, permanent assignment, lieutenant, etc.).

For each case and control, the daily work assignment logs for the month including the case's date of illness were searched. Details of the work assignments on the case's date of illness and seven days prior to that were recorded, including section of beach, tower, and hours at each tower.

Descriptive analyses used SAS computer programs,[8] and conditional logistic regression estimates[9] used BMDPLR.[10]

Results

During the seven-year study period, 112 acute compensable illnesses occurred among the Los Angeles County lifeguards. The peak year was 1980 with 28 claims, while 1985 and 1986 had only eight claims each. Most claims were due to otitis externa and unspecified ear infections (N = 69). Other diagnostic categories were otitis media (N = 15), dermatitis (N = 6), rash (N = 2), skin infection (N = 6), and conjunctivitis (N = 5).

The Department of Beaches and Harbors of Los Angeles County has divided the county beaches into three sections for administrative purposes (Figure 1): Southern, Central, and Northern. The age-adjusted odds ratios (ORs) for working at each section of beach compared with not working at all (Table 1) showed a very strong association between working Southern section beaches and acute illness. Similar associations were observed with illness restricted to otitis externa or unspecified ear infections (OR for Southern section = 12.5, 95% CI = 2.9, 53.4). Ten cases and 41 controls did not work at all during the reference week. The odds ratio for working as a Los Angeles County lifeguard at any location was 8.3.

Since ear infections are related to the amount of time spent in the water,[7,11] we also analyzed the effect of beach location using only those pairs where both subjects worked at all during the reference week (N = 64) with working as a proxy for swimming. The southernmost beaches within the bay proper were most strongly associated with acute illness. To remove the effect of 13 repeated ear infections occurring in different years to some "disease-prone" individuals, we

TABLE 1—Age-Adjusted Conditional Disease Odds Ratios for Working at Various Beaches

Beach	Odds Ratio (95% CI)
All beaches combined	8.3 (2.9, 23.5)
Southern section beaches combined	14.4 (4.7, 44.8)
Cabrillo Beach-White Point	5.4 (0.8, 36.2)
Torrance-Redondo Beach	17.0 (2.9, 100.2)
Hermosa Beach	36.4 (6.7, 198.2)
Manhattan Beach	15.7 (2.8, 89.7)
Dockweiler State Beach	15.6 (2.2, 111.0)
Central section beaches combined	5.3 (1.8, 15.5)
Venice	10.7 (2.0, 57.2)
Santa Monica	7.0 (1.9, 24.6)
Will Rogers	6.4 (0.4, 103.8)
Northern section beaches combined	4.4 (1.4, 14.1)

repeated the analysis excluding these episodes. The odds ratios were diminished slightly but again the southernmost beaches within the bay were most strongly and significantly associated with illness.

Discussion

All illnesses studied for this report were compensated through Los Angeles County's workers' compensation system, and were therefore physician-diagnosed. Almost certainly less misclassification occurs with such data than with self-reports of symptoms.[2,6,12,13] On the other hand, workers' compensation reports probably yielded an underestimate of the total number of work-related illness events. It is possible that lifeguards who experienced minor symptoms did not seek medical attention or might not have associated symptoms with their jobs. This may explain the absence of gastrointestinal illnesses.

Although it is possible that lifeguards working at certain beaches were more likely to report acute illness, we know of no specific work pattern that would create such a bias. Also we noted a high odds ratio in Venice Beach in the Central section, which is administratively distinct from the Southern section.

We lacked data to control for other water exposures, e.g., swim workouts at the worksite or recreational exposure to the bay at the worksite or other locations. We had no data on swimming habits, such as head submersion, associated with ear problems.[11,13] Matching on job class partly controlled for differences in job tasks which could affect the subjects' amount of exposure to water while at work. For example, temporary lifeguards cover most of the tower assignments and therefore may have been required to enter the water more often, on average.

The reason for the decline in work-related acute illnesses over the study period is not known. Lifeguards may have begun mitigating their risk of illnesses by reducing their water exposures or by changing swimming habits.

A recent report on Santa Monica Bay indicated that storm drains and creeks are responsible for the levels of the indicator bacteria (enterococci and coliforms) measured at shoreline. Whether these bacteria are indicative of human pathogenic agents is unclear.[14] Using maps provided by the Los Angeles County Department of Public Works, we calculated the number of storm drains (500 feet or longer) or creeks per 10,000 linear feet of coastline (Table 2). These ratios were generally higher in Southern beaches, except for Dockweiler State Beach; but that beach includes the outlet for the largest drain into the bay which may contaminate a wider area than most drains. A recent raw sewage spill into this drain resulted in beach closures which included Venice and Dockweiler beaches.[15] We present this ecologic association as one possible explanation for our study results, recognizing that microbial contamination of Santa Monica Bay is a complex, multifactorial, and only partially understood process.

The findings of this study, the first of its kind, suggest that acute illnesses among lifeguards were associated with Southern Santa Monica Bay work locations.

ACKNOWLEDGMENTS

The authors would like to acknowledge the Department of Beaches and Harbors of Los Angeles County (California) and in particular Eric Bourdon, Tom Marvin, and JoAnn Hucle without whose help this study could not have been conducted. Additionally, we are grateful to Jess F. Kraus, PhD, for

TABLE 2—Storm Drain and Creek Outlets into Santa Monica Bay and other Los Angeles County Beaches

Beach Areas	Number of Storm Drains and Creeks per 10,000 Feet of Coastline	Characteristics of Catchment Area	Comments
Southern Section			
Cabrillo Beach-White Point	7.2	Residential and commercial	Los Angeles Harbor ship channel empties east of Cabrillo Beach
Torrance-Redondo Beach	7.9	Residential and some commercial	Narrow catchment area; mostly winter rain season flow
Hermosa Beach	9.0	Residential and some commercial	Narrow catchment area; mostly winter rain season flow
Manhattan Beach	5.5	Residential and some commercial	Narrow catchment area; mostly winter rain season flow
Dockweiler State Beach	2.2	Residential, commercial, and heavy industrial	Ballona Creek at Northern edge of beach drains extremely large area and occasionally drains raw sewage spills
Central Section			
Venice	3.1	Residential and commercial	Moderate catchment area
Santa Monica	4.4	Residential, commercial, and industrial	Moderate to large catchment area
Will Rogers	4.4	Residential and unimproved parkland	Moderate to large catchment area
Northern Section	2.9	Sparse residential and parkland	Large catchment area; some raw sewage contamination from septic tanks

Master's Degree Program
Public Health Ophthalmology

A special Master's Degree Program in Preventive Ophthalmology will again be offered, during 1990-1991 by the Johns Hopkins Medical Institutions under the auspices of its Dana Center for Preventive Ophthalmology, a World Health Organization Collaborating Center.

The program is designed for individuals interested in initiating, developing, and providing leadership to national or regional blindness prevention activities and in conducting serious clinical epidemiologic research. Five to ten places are available for participants from developing and developed countries. A small stipend may be available to some participants to help defray living expenses.

For further information write:

Program Coordinator, Preventive Ophthalmology Program, DCPO, Wilmer Institute, Room 120, Johns Hopkins Hospital, 600 N. Wolfe Street, Baltimore, MD 21205.

The Reliability of Health Risk Appraisals: A Field Trial of Four Instruments

KEVIN W. SMITH, MA, SONJA M. MCKINLAY, PHD, AND JOHN B. MCKINLAY, PHD

Abstract: A field trial was conducted to evaluate the reliability of four widely used health risk appraisals (HRAs). A total of 338 randomly selected adults aged 25 to 65 years residing in the Boston metropolitan area completed an HRA on two occasions seven to 12 weeks apart. Test-retest reliability was assessed by comparing self-reported baseline risk scores to follow-up scores for heart attack risk and selected coronary heart disease risk factors. Respondents generally gave consistent reports for family history, cigarette smoking, and relative weight (test-retest $r > .75$), but self-reported scores for physiologic status (blood pressure and cholesterol) and lifestyle (diet, physical activity, and stress) were much less stable. Coefficients for heart attack risk and appraised age ranged from .43 to .87 for the four HRAs. The reliabilities of two self-scored instruments were greatly reduced by mathematical errors made by respondents when computing their heart attack risk scores. These results were not affected by the length of the follow-up period (seven to 12 weeks). (*Am J Public Health* 1989; 79:1603–1607.)

Introduction

Reliability refers to the degree to which measurements are affected by random error. Random error effects may be assessed by the stability of the measures or scores produced by an instrument from one time period to another. The higher the correlation between scores measured at two points in time under identical conditions, the more reliable the instrument.[1]

For health risk appraisal (HRA) instruments designed to provide estimates of mortality or morbidity risk for various diseases, reliability is an important issue for several reasons. First, reliability is related to the validity of an HRA. Random errors in self-reported health status and physiologic measures will decrease the accuracy of an HRA's estimate of disease risk. Second, HRAs are frequently employed to evaluate the effectiveness of health promotion programs. If HRA scores are unstable during the pre- to post-program periods, changes attributable to the intervention may be indistinguishable from unreliability in the instrument itself. Moreover, respondents may be inclined to dismiss HRA estimates if they find that their risk scores fluctuate dramatically from one time period to another.

In recent years, several studies have raised questions about the reliability of HRA data. Best and Milsum found that participants in a smoking cessation program reported many improbable changes in their body frame size, medical history, and family history after six months.[2] Sacks and his associates found that only 15 percent of the subjects in a clinical trial gave consistent responses to all HRA items at both baseline and follow-up interviews.[3] On the other hand, some studies have reported test-retest reliability coefficients exceeding .7 for selected risk factors and overall risk estimates, especially for follow-up periods of short duration (three days to one month).[4–7]

Several methodological limitations associated with these studies make it difficult to generalize about HRA reliability.

- First, some investigators have reported only the percentage of respondents choosing the same response category for a particular item at both points in time. This is inadequate for assessing the degree of reliability because it does not take into account the differences between the risk scores assigned to the categories. In many instruments, selecting an adjacent category for a particular item produces little or no change in the risk score for that item; in other cases, the difference may be substantial.
- Second, much of the previous work has been based on limited samples of self-selected volunteers. In some instances, fewer than 30 subjects were involved in the analyses.[5] It is not clear whether the results from these studies are representative of the general population.
- A third problem common to all test-retest analyses is that reliability may be confounded with actual change. Scores for the same individual may differ from one administration to another because other behavioral changes have occurred in the intervening period.
- Finally, the effect of the length of the follow-up period on reliability coefficients for HRAs has yet to be established.

Recognizing these shortcomings, several recent reviews of the status of risk appraisal methods have called for more comprehensive investigations of HRA reliability.[8–10]

In response to these issues, a field trial was designed to assess the reliability and validity of four HRAs. For each HRA, this paper examines:

- the proportion of respondents choosing the same risk factor categories at both administrations,
- test-retest reliability coefficients for individual risk factors and total risk scores,
- the effect of behavioral changes occurring during the follow-up interval on reliability coefficients, and
- the influence of the length of the follow-up period on changes in risk scores.

Methods

The field trial was conducted from January to November 1987. Subjects were identified through random digit dialing of 15 telephone exchanges in the Boston, Massachusetts metropolitan area. Five exchanges were drawn from each of three strata comprising calling areas with below average, average, and higher than average household incomes. One adult was selected at random from each household and screened for eligibility. The study was restricted to persons between the ages of 25 and 65 at last birthday who did not

© 1989 American Journal of Public Health 0090-0036/89$1.50

have a history of coronary heart disease, diabetes, or hypertension, so that the sample would reflect the typical target population for HRAs that contain coronary heart disease components. An introductory letter explaining the purpose of the study was sent to each respondent who provided an address at the time of the screening.

Eligible cases were then contacted by a trained field technician to arrange a home visit. During the visit, the technician administered a standardized personal interview and one of the four HRAs evaluated by the project. Field technicians were not permitted to help respondents complete HRA items or compute risk scores. Subjects were reinterviewed seven to 12 weeks after the initial visit. Fifty-five percent of the eligible cases (the reliability group) were asked to complete the same HRA at follow-up. The follow-up interval was designed to be long enough to minimize memory effects, but short enough so that major changes in lifestyle and behavior would be unlikely to occur. The analyses presented in this paper are restricted to field trial participants completing the same HRA at both baseline and follow-up.

Four widely-used HRAs were chosen to represent the major types of instruments that are currently available:[11]

1) Health Risk Appraisal (Centers for Disease Control)
2) The Heart Test (Arizona Heart Institute)
3) RISKO (American Heart Association)
4) Determine Your Medical Age (Blue Cross/Blue Shield, NY)

Each instrument requires a respondent to select categories that best describe personal habits, physiologic status, and medical history. Point values or weights associated with these categories are then combined to produce an overall estimate of risk. In these four HRAs, overall risk is summarized by either a heart attack risk scale, where higher values represent greater risk, or by appraised age. Appraised age is the age of adults with the same all-causes mortality risk as a particular individual. The items and range of risk scores for each HRA are shown in the Appendix.

Reliability analyses were conducted by comparing the baseline scores for individual risk items, heart attack risk, and appraised age with the values chosen by the same respondent at follow-up. Consistent with psychometric practice, Pearson correlations between the baseline and follow-up risk scores served as reliability coefficients.[12] These correlations are approximately the same as weighted Kappas with weights equal to squared deviations between baseline and follow-up risk scores.[13,14] For four items, the influence of other changes occurring during the follow-up period was assessed by computing test-retest correlations only for those who said, in another part of the interview, that their behavior had not changed since baseline. For relative weight, diet, and physical activity, these correlations were restricted to those reporting that their behavior at follow-up was "about the same" as it had been at baseline. Analyses for smoking were based only on those who reported smoking the same number of cigarettes at both interviews. Finally, follow-up risk scores were regressed on baseline scores and the number of days that had elapsed between the dates of the baseline and follow-up were computed to evaluate the impact of the length of the follow-up interval on reliability.

In the absence of established minimum standards for test-retest coefficients, correlations of .8 or greater were adopted a priori as a criterion level in this study. This level is equivalent to the informal standard for internal consistency used in many social science applications.[12] Sample sizes for each of the four HRA groups in the field trial were designed to have sufficient power to detect a difference between the standard of .8 and a correlation of .65 or less, which was regarded as unacceptably small for reliable items.[15]

Results

Baseline interviews were completed by 732 of 1,276 eligible adults (57.4 percent) contacted for the field trial. Table 1 compares the demographic characteristics reported during the telephone screening by reliability group participants, other participants in the field trial, and eligible subjects who declined to participate. All three groups were similar with respect to these measures; a logistic regression analysis of response rates indicated that the probability of obtaining a completed baseline interview was not affected by these characteristics (likelihood ratio statistic = 5.70, df = 6). Of the 403 reliability group subjects interviewed at baseline, 338 (84 percent) consented to a follow-up interview and completed HRAs at both administrations (n = 83 to 87 persons for each instrument).

Response Category Comparisons for Risk Items

Table 2 compares the percentage of respondents who chose the same category for eight major risk items at both baseline and follow-up. The marginal distributions of these items were similar at each administration. Participants were generally very consistent in their reports of family history and smoking. Choices for relative weight were consistent at least 70 percent of the time. The lowest agreement rates occurred for lifestyle factors such as diet, stress, and physical activity, which may change even over short periods of time.

The consistency of blood pressure and cholesterol reports are more difficult to evaluate. These reports were the same at both administrations at least 87 percent of the time for two of the three self-scored instruments. Determine Your Medical Age, however, merely specifies a cut-off level so that only two choices were available to respondents. Similarly, the Arizona Heart Test specifies only three categories for blood pressure: normal, borderline, or high. The agreement rates for RISKO were below 70 percent, but this instrument offered more category options than the others. Like most of the Geller/Gesner mortality risk HRAs, the Centers for Disease Control (CDC) instrument requests actual blood pressure readings and cholesterol levels. The majority of participants left these items blank because they did not know

TABLE 1—Demographic Characteristics of Field Trial Participants and Nonparticipants[a]

Characteristics	Reliability Group Participants (N = 403)	Other Field Trial Participants (N = 329)	Non-Participants (n = 544)
Age (years)	38.8 (10.6)	40.0 (10.8)	40.2 (11.1)
Percent female	55.8 (49.7)	59.9 (49.1)	60.5 (48.9)
Percent Black/Hispanic	6.7 (25.1)	10.7 (30.9)	8.2 (27.4)
Income (thousands)[a]	41.1 (10.4)	41.2 (11.1)	40.5 (10.1)
Self-reported health status[b]	2.06 (.94)	1.92 (.86)	2.06 (.91)
Worry about health[c]	2.54 (.83)	2.54 (.85)	2.52 (.84)

[a]Mean and (standard deviation)
[a]Mean household income in subject's telephone exchange
[b]5-point scale; 1 = excellent; 5 = poor
[c]4-point scale; 1 = not at all, 4 = most of the time

TABLE 2—Percent of Respondents Choosing Same Risk Item Category at Baseline and Follow-up by HRA

Risk Items	Arizona Heart Institute	CDC	Determine Your Medical Age	RISKO
Family History	91.9	96.4	86.2	—
Smoking	82.6	91.6	83.9	85.7
Relative Weight	79.8	78.0	71.3	80.8
Physical Activity	64.3	73.5	65.5	—
Blood Pressure	94.6	NR	87.4	58.4
Cholesterol	—	NR	94.3	64.8
Stress	65.6	—	—	—
Diet	72.3	—	55.2	—

NR = value not reported by majority of respondents

the appropriate values. For this reason, no results for these two risk factors are presented for CDC in Table 2.

Test-Retest Correlations for Risk Items

The proportion of respondents selecting the same response categories at two points in time is, at best, a crude indicator of risk factor reliability because it fails to account for the degree of risk involved.[16] For the self-scored instruments, different response categories sometimes have the same risk values, so that selecting different categories may not result in any change in the risk score for that item. To provide a more sensitive measure of reliability, test-retest correlations were computed for each HRA on the basis of the scores associated with each risk factor category. The CDC instrument differs from the others in that risk weights rather than point values are assigned to item categories.

Table 3 shows the test-retest correlations for the risk scores associated with the eight HRA items. Correlations between baseline and follow-up risk scores for family history, smoking, and relative weight exceeded .75 for all applicable instruments. The remaining five items all had estimated reliability coefficients that were significantly lower than the criterion level of .8 for at least one HRA. In spite of differences in question wording and risk scores, the reliability estimates for a specific item were usually quite similar among the four HRAs.

Effects of Behavioral Change on Reliability

Discrepancies between pre- and posttest reports do not always mean that information has been reported unreliably because behavior may have changed since the baseline interview. Test-retest correlations were therefore computed for selected items only for those respondents who claimed their behavior had not changed during the follow-up interval. These items were weight (relative weight), exercise level (physical activity), sodium, fat, and caloric intake (diet), and smoking risk (only those who gave the same number of cigarettes per day at both interviews).

Results for these respondents are summarized in Table 4. Compared to the coefficients for all cases (Table 3), behavioral changes had the greatest impact on reports of dietary habits. The estimated reliabilities increased slightly (.04 on average) for smoking and relative weight, but were virtually identical for physical activity risk scores. Therefore, with the possible exception of dietary practices, it would appear that behavioral changes did not greatly influence the reliabilities of these risk items.

Test-Retest Correlations for Heart Attack Risk and Appraised Age

In the process of collecting data during the field trial, it quickly became apparent that many respondents who received self-scored HRAs had difficulty computing these risk scores. Heart attack risk scores and appraised age values were therefore checked for accuracy by project staff. Eighty-seven percent of those completing the Arizona Heart Institute HRA were able to calculate the correct score compared to 75 percent of the RISKO respondents and only 42 percent of those completing Determine Your Medical Age. These rates reflect the mathematical skills required by each instrument—the Arizona Heart Institute HRA involves adding point values, RISKO requires both addition and subtraction, while respondents must add, subtract and divide scores to determine their "medical" age. Error rates were also influenced by the educational attainment of respondents. Those without four-year college degrees were twice as likely as college graduates to make computational mistakes on both the RISKO (22.5 percent compared to 9.0 percent) and Determine Your Medical Age (61.4 percent compared to 30.0 percent) HRAs.

Test-retest reliabilities for heart attack risk scores and appraised age were calculated separately for the risk scores actually reported by respondents as well as score totals corrected for mathematical mistakes. The coefficients for reported risk scores were .87 for the Arizona Test HRA, .84 for the CDC HRA, and .74 for Determine Your Medical Age. The correlation between baseline and follow-up scores reported by RISKO respondents (r = .43), on the other hand, was significantly lower than the criterion level of .8. For this instrument, even minor addition or subtraction errors can produce misleading estimates of whether a person is above or below the average risk for heart disease. When these errors were corrected, RISKO's estimated reliability increased to .76. Correcting computational errors also produced a marked improvement in the reliability of Determine Your Medical

Age (from r = .74 to r = .99) but not the Arizona Heart Institute HRA, for which mathematical mistakes were much less common. While computational mistakes are not an issue with computerized Geller/Gesner method HRAs like the CDC's, these instruments typically insert risk weights of 1.0 for any unknown risk factors. This practice artificially inflates reliability coefficients.

Length of Follow-up Period

The reliability of most measurements decreases over time. In this study, the interval between baseline and follow-up interviews ranged from seven to 12 weeks (49 to 84 days). The final set of analyses was designed to determine whether the reliability of respondents' self-reports declined as the length of the follow-up period increased. To address this issue, follow-up risk scores were regressed on baseline scores and the number of days that had elapsed between the baseline and follow-up interviews. The regression results (Table 5) indicate that the length of the follow-up interval had little impact on the follow-up scores for any of the risk measures. However, this interval was comparatively short and had limited variability among respondents.

TABLE 5—Multiple Regression of Follow-up Risk Score on Length of Follow-up Interval* Adjusted for Baseline Risk Score: Unstandardized regression coefficient and (standard error)

Discussion

In this field trial, respondents generally gave consistent reports for three risk items: family history, cigarette smoking, and relative weight. Self-reports of physiological status (blood pressure and cholesterol) and lifestyle (diet, physical activity, and stress), on the other hand, were much less consistent between the baseline and follow-up interviews. The consistency of physical activity reports may have been diminished by seasonal variations in exercise patterns.

There were some important differences among the instruments with respect to the reliabilities of heart attack risk scores and appraised age. The test-retest coefficients for the Arizona Heart Institute and Centers for Disease Control HRAs both exceeded .84, but were only .74 and .43 for Determine Your Medical Age and RISKO, respectively. The correlations for the latter two instruments were reduced by mathematical errors made by respondents when computing their risk scores. Reliability coefficients for the CDC HRA, on the other hand, may be overstated due to the practice of substituting risk weights of 1.0 for blood pressure and cholesterol whenever the actual values are unknown.

Inconsistencies between baseline and follow-up values were more likely to be attributable to unreliable reporting on the part of respondents rather than to actual changes in risk factor status. Changes in risk scores were not affected by variations in the length of the follow-up period. However, testing reactivity could have lowered reliability levels. Completing an HRA for the first time can motivate respondents to obtain more accurate information about family history, blood pressure, or cholesterol, so that follow-up responses will then appear to be inconsistent.

The results of the field trial indicate that the reliability of HRA risk scores can vary greatly from one instrument to another. These findings have several implications for health educators using HRAs. First, computation errors may severely reduce the reliability of self-scored instruments. Computerized HRAs may therefore be the most desirable type unless manual calculations can be routinely checked for errors. Second, additional work needs to be done to improve the measurement of specific risk factors, particularly physical activity levels, dietary practices, and physiologic status. The reliability of blood pressure and cholesterol levels can be increased by measuring these values during physical examinations rather than relying on self-reports. Finally, as the reliability of an HRA declines, it becomes increasingly difficult to distinguish changes in risk status from random reporting errors. This is particularly important for investigators interested in assessing the effects of health promotion interventions because unreliability makes intervention effects more difficult to detect. Therefore, only HRAs for

which reliability can be demonstrated should be considered for evaluations of the effectiveness of these interventions.

APPENDIX

Risk Scores Ranges by HRA

	Arizona Heart Institute (self-scored)	Centers for Disease Control (computer-scored)	Determine Your Medical Age (self-scored)	RISKO (self-scored)
Heart Attack Risk	0–50	2–21,969	—	0–27
Appraised Age	—	18.4–65.1	12.0–70.6	—
Family History	0–5	.9–1.2	−30–15	—
Smoking	0–10	.8–2.1	−6–24	−2–4
Relative Weight	0–3	.8–1.6	−6–24	−2–3
Physical Activity	0–3	.6–2.5	−12–12	—
Blood Pressure	0–6	.4–1.1	0–12	−5–6
Cholesterol	—	.5–1.6	0–6	−3–3
Stress	0–6	—	—	—
Diet	0–6	—	−6–18	—

The Centers for Disease Control (CDC) HRA, which requires computer processing, provides probability estimates for the 12 leading causes of death as well as appraised age based on the Geller/Gesner method.[17]

The Arizona Heart Institute Test and RISKO are self-scored instruments focusing on heart attack risk.

In the Determine Your Medical Age HRA, appraised age is calculated by adjusting an individual's chronological age for medical history and lifestyle factors.

Call for Papers:
Risk Management in Rural Health Care

The American Society for Healthcare Risk Management has issued a call for papers to be considered for its Fall 1990 issue of *Perspectives in Healthcare Risk Management*. Emphasis should be on the issues and problems inherent in rural health care risk management, as well as on suggestions for how to deal with them effectively. Topics and approaches include but are not limited to: credentialing issues, peer review, conflict of interest, patient transfer issues, swing-beds, risk pooling, and quality assurance/risk management integration.

Authors should submit a one-page abstract and detailed outline of an original article on any area of risk management in rural health care delivery settings. *Abstracts and outlines must be received no later than March 5, 1990.* Authors of those abstracts selected for further consideration will be asked to submit their completed papers (not to exceed 20 typewritten, double-spaced pages) by June 4, 1990. Manuscripts will be accepted with the understanding that their content is unpublished and not being submitted for publication elsewhere. Send abstracts to:

Accuracy of Perceptions of Heart Attack Risk: What Influences Perceptions and Can They Be Changed?

NANCY E. AVIS, PHD, MSHYG, KEVIN W. SMITH, MA, AND JOHN B. MCKINLAY, PHD

Abstract: Using perceived risk of a heart attack, we examined the relative importance of perceived risk factors and sociodemographic variables on subjects' perception of heart attack risk, the relationship between perceived and objectively measured heart attack risk, and the effect of health risk appraisal (HRA) feedback on risk perceptions. Data derive from a random sample of 732 Greater Boston, Massachusetts area men and women ages 25–65 years, who participated in a field trial of health risk appraisal instruments. At baseline and approximately two months later, all respondents completed a questionnaire assessing their own health-related behavior, risk factors, and perception of heart attack risk. At baseline, respondents also completed one of four HRA instruments. Physiologic measures of cholesterol, blood pressure, and weight were taken at either baseline or follow-up visit. Results showed that respondents used established risk factors in estimating overall risk; that compared to objective measures of risk, a high percentage of respondents displayed an optimistic bias; and that HRA feedback had some effect on perception of heart attack risk for those at high risk. Implications of these results for health promotion are discussed. (*Am J Public Health* 1989; 17:1608–1612.)

Introduction

A person's beliefs about his or her perceived susceptibility to a condition or disease figure prominently in models of health behavior such as the Health Belief Model,[1,2] the Theory of Reasoned Action,[3] Subjective Expected Utility Theory,[4,5] and Protection Motivation Theory.[6,7] These models assume that perceived susceptibility (also referred to as vulnerability or risk) is essential in motivating behavior.

Previous research, however, has shown that people tend to underestimate their own risk of developing certain conditions or diseases[8–17]—or they have what Weinstein[13] refers to as an "optimistic bias." This underestimation has important implications for health promotion and behavior change programs. If people do not perceive themselves as vulnerable to a disease or condition, they are less likely to adopt recommended behaviors.[1,18] It is therefore important to understand what determines a person's perception of risk and how these perceptions can be made more realistic.

Most of the research on perceived susceptibility uses comparative risk judgments to examine how people compare their risk for a particular condition or disease to that of their peers.[8–10,13–16] This method, however, does not address the accuracy of an individual's risk perception. In an attempt to examine this issue, Weinstein conducted two studies[15,16] in which an individual's comparative risk judgments were correlated with his or her relevant risk factors. Weinstein found that these associations were often weak or nonexistent. However, the measures of risk factors lacked precision and were based only on self-report. In addition, each risk factor was separately correlated with perceived risk, rather than combined to form an overall estimate of risk. One purpose of this study is to use epidemiologically based models to examine the relation between perceived risk and objectively measured risk for heart attacks.

Optimistic biases may have several sources. They may be due to cognitive errors (e.g., lack of information or experience with a condition) or motivational needs (e.g., self-esteem enhancement or defensive denial).[16] To the extent that they result from cognitive errors, individualized feedback about risk may overcome these biases. Health risk appraisal instruments (HRAs) are designed to estimate a person's mortality or morbidity risk for various diseases based on characteristics such as medical history, blood pressure, and smoking habits.[19] One of the goals of HRAs is to provide risk-related feedback that will enable a person to reduce risk in areas amenable to modification.[20] Another purpose of this study is to examine the effect of individualized risk feedback on risk perception.

Methods

Procedure and Sample

The data used in this study were collected during a field trial of health risk appraisal instruments conducted by the Cambridge Research Center of the American Institutes for Research in 1987. Detailed descriptions of the procedure and sample characteristics are reported in the article in this issue by Smith, McKinlay, and McKinlay.[21] Briefly, respondents were identified through random digit dialing of residential households in 15 neighborhoods and towns in the Boston metropolitan area. Eligibility was restricted to adults between the ages of 25 and 65 who did not have a history of coronary heart disease, diabetes, or hypertension. Following a telephone screening, baseline interviews were conducted by trained field technicians in respondents' homes. After completion of the baseline interview, respondents were randomly assigned to complete one of four risk appraisal (HRA) instruments (CDC, Arizona Heart Test, RISKO, and Determine Your Medical Age), or were assigned to a "no HRA" condition. (See Smith, *et al*,[21] for details of the HRAs). Field technicians were not permitted to help respondents complete HRA items or compute risk scores. Follow-up home visits were conducted seven to 12 weeks after the baseline to monitor changes in health status, health practices, and medical care utilization. During one of the two home visits (randomly determined), technicians measured blood pressure, height and weight, and drew a venous blood sample for cholesterol analysis.

Measures

Perceived risk of heart attack or stroke was assessed by the question: "Compared with persons of your own age and

sex, how would you rate your risk of having a heart attack or stroke within the next 10 years?" Respondents answered on a 5-point scale ranging from "much lower than average" to "much higher than average."

Respondent characteristics that might be related to perceived risk were divided into sociodemographic characteristics, self-perceptions of health, and cardiovascular risk factors. Sociodemographic factors included education, race, gender, and age (although gender and age can also be considered risk factors). Self-perception of health status was measured on a 5-point scale ranging from excellent to poor.

Cardiovascular risk factors were measured as follows. Family history of heart disease was based on having a biological parent die of heart disease or stroke before age 65. Smoking was based on self-report of how many cigarettes per day the person currently smoked. Self-report of smoking is generally thought to be reliable, especially for respondents who are not in a smoking reduction program.[22] All respondents who smoked at least one cigarette per day were classified as smokers. The Harvard Alumni Activity Scale,[23] which measures recreational physical activity in terms of kilocalories (kcal) expenditure per week, provided the measure of exercise. Stress was determined by the number of stressful events (e.g., death of partner or spouse, divorce, loss of job, major change in health of family member), as derived from the Holmes and Rahe Scale[24] that were reported by the respondent as occurring within the past two months. Self-reports of weight, cholesterol, and blood pressure as compared to average were also obtained.

Results

Perceived Heart Attack Risk

Almost 56 percent of the respondents rated their risk as lower than average, 29 percent rated it about average, and only 13 percent rated their risk as higher than average. With over half the respondents rating their risk as lower than average, these results support previous findings that people tend to rate their own risk as lower than that of their peers—that people have an optimistic bias. Although respondents were healthier than their peers because those with hypertension, diabetes, and other chronic diseases were excluded from the study, this optimistic bias is confirmed when compared to objective risk (see below).

To examine the relative importance of perceived risk factor status, sociodemographic factors, and perceived health in people's perception of heart attack risk, a multiple regression analysis was performed in which perceived risk of a heart attack reported at baseline was the dependent variable. These results show associations between perceived heart attack risk and the following risk indicators: number of cigarettes smoked, death of a parent due to heart disease; and self-assessments of weight, blood pressure and cholesterol compared to average levels (see Table 1). Neither amount of exercise nor number of recent stressful events was related to perceptions. These results suggest that people do make use of cardiovascular risk indicators in estimating overall risk. These risk factors accounted for 24 percent of the variance in perceived risk. Self-reported health and education were also positively related to perceived risk and, combined with the risk factors already included, accounted for 30 percent of the variance. The correlation between self-reported health and risk is partly a function of the way in which self-reported health was scored (i.e., a 5-point scale). The Pearson correlations between these variables and perceived risk show a pattern similar to the multiple regression, suggesting that multicollinearity is not a problem in this analysis.

TABLE 1—Results of Multiple Regression on Variables Related to Perceived Heart Attack Risk at Baseline

Variable	Unstandardized Regression Coefficient	S.E.
Self-reported risk factors		
Cigarettes smoked per day	.02	.00
Cholesterol relative to average	.24	.05
Weight relative to average	.23	.05
Death of parent due to CHD	.38	.10
Blood pressure relative to average	.19	.06
Exercise	−.03	.03
Number of recent stressful events	−.02	.06
Perceived Health	.34	.05
Sociodemographic Factors		
Education	.08	.03
Age	−.01	.00
Minority	−.22	.13
Female	.12	.08

Education was positively related to perceived risk in the regression model, yet had a negative Pearson correlation with perceived risk. Because Pearson correlations revealed that education was related to self-perceived health, exercise, smoking, and blood pressure, and because we thought education might modify these effects, we also performed a multiple regression that included the interactions between education and these variables. The only significant result was an interaction between education and smoking, such that those with more education who smoked perceived their risk to be greater.

Perceived and Objective Heart Attack Risk

The risk equation from the new Carter Center Healthier People HRA was used to obtain an objective measure of coronary heart disease risk.[25] This logistic risk model builds on the results of the Risk Factor Update Project but takes into account more recent epidemiological data from the Framingham Heart Study. The variables included in the logistic equation to predict mortality from myocardial infarction are: sex, total cholesterol, age, number of cigarettes smoked per day, systolic blood pressure, relative weight, HDL cholesterol, and presence of diabetes. Family history and exercise are not included in the model because it is thought that their effects operate through other risk indicators in the model (cholesterol, blood pressure, and weight).[25]

Because respondents were instructed to answer the risk perception question in comparison to other people of the same age and sex, we adjusted the objective measure of risk for age and sex. Each respondent received a risk ratio which was based on the logistic estimate from the model divided by the average risk for that person's age, sex, and race. A ratio of 1.0 meant a person was at average risk for his or her age, sex, and race.

Respondents were then classified as to whether they were at above average, average, or below average risk. A ratio below .75 was considered below average risk, .75 to 1.25 average risk, and over 1.25 above average. In order to create a symmetric distribution, these ratios were transformed onto a log scale, in which the cut-offs became ln(.75) and ln(1.33). These ratios represent equal "risk distances" from the null value of 0.0 on the log scale [ln(1.33) = −ln(.75) = .29]. Using this distribution, 39 percent of the respondents were classi-

fied as below average risk, 24 percent as having average risk, and 36 percent as above average risk.

Perceived risk was then compared with the objectively measured risk categories. In Table 2, the rows indicate the percentage of respondents in each risk perception category, while the columns indicate the percentage of respondents in each objectively measured category. Summing over cells, a total of 42 percent of the respondents underestimated their risk (15% + 17% + 10%), while only 18 percent (11% + 3% + 4%) overestimated risk, and 40 percent (25% + 9% + 6%) were accurate. Based on these results, when using an objective measure of risk, this analysis also found evidence of an optimistic bias—a high percentage of respondents underestimated their risk.

We next performed two logistic regressions: one to predict the probability that risk was overestimated (pessimists), and the other to predict underestimation of risk (optimists). Variables included as predictors were the same variables listed in Table 1 that were used to predict perceived heart attack risk. The variables associated with pessimism were death of parent due to heart disease (O.R. = 2.72, 95% CI = 1.52, 4.87), self-assessed health status (O.R. = 1.80, 95% CI = 1.25, 2.58), and age in years (O.R. = 1.06, 95% CI = 1.02, 1.08). Thus, pessimists were more likely to be in worse health, have had a parent die of heart disease, and be older. The result for death of a parent may reflect the fact that people give weight to this risk factor while the Carter Center model does not include it. The variables that predicted optimism were age (O.R. = .90, 95% CI = .87, .92) and education (O.R. = .80, 95% CI = .66, .98). Those who were younger and had less education were more likely to be optimists.

Effect of Health Risk Feedback

Table 3 shows the effect of feedback on *change* in perceived risk. In this table, the columns indicate the type of feedback received, while the rows indicate whether perceived risk increased, did not change, or decreased from baseline to follow-up. The numbers in parentheses are the percentage of respondents who did not change their perceptions and whose perceptions accurately reflected their HRA feedback. In reading this table, it is important to keep in mind that those who received feedback that they were below average risk should have either been accurate or decreased their perceived risk, while those who received feedback that they were above average risk should have either been accurate or increased their perceived risk.

As seen in Table 3, the majority of respondents did not change their risk perceptions. Those who changed the most received feedback that they were above average risk. They were more likely to increase their perceived risk (21.8 percent of those receiving above average feedback). This group, however, was also the least accurate in their risk perceptions. Those who received feedback that they were at below average or average risk, or did not receive any HRA feedback were as likely to increase their perceived risk as to decrease it. It should be pointed out that because respondents tended to underestimate their risk at baseline, there were more respondents in the "above average" feedback category with the potential to change. While HRA feedback had its greatest effect on those at above average risk, 12 percent of those with above average risk changed their perceptions in the opposite direction of the feedback.

TABLE 2—Relationship between Perceived and Estimated Risk as Measured by the Carter Center Model

	Risk Ratio			
Perceived Risk[a]	Below %	Average %	Above %	Total

(accurate)		(60.8)	(26.6)	(16.8)
Decrease	13.5	11.0	10.6	11.9
	100%	100%	100%	100%
n	89	347	94	101

[a]Scored 1 = below average, 2 = average, 3 = above average.

To further explore whether receipt of HRA feedback altered risk perception, we looked at follow-up risk perception as a function of baseline risk perception, the same variables examined in the baseline risk perception analysis (this time using follow-up responses) plus HRA feedback. A multiple regression was performed in which follow-up risk perception was regressed on baseline risk, follow-up perceptions of risk factors, sociodemographic factors, perceived health, and HRA feedback. Feedback was measured by a scale relating HRA risk category to the respondent's initial perception. The respondent's initial perception was taken into account because feedback should only have an effect when it differs from the person's original perception. The feedback scale ranged from 1 to 5, where 1 meant the HRA risk category was much lower than the individual's perception, and 5 meant the HRA risk category was much higher than the respondent's perception.

These results, shown in Table 4, reveal only feedback from the Arizona Heart Institute (AHT) HRA had a significant impact on heart attack risk perception. Compared to the other three HRAs, the feedback from this HRA was presented in a concrete fashion directly related to heart disease risk. Respondents were clearly told that they were above average, average, or below average risk for developing heart disease. Thus, respondents may be more likely to understand and use the feedback from the AHT.

Risk Perception and Behavior

Although it was not a primary purpose of the study, because data on respondents' risk-related behavior were available, it was possible to examine the relationship between change in perceived risk from baseline to follow-up and corresponding behavior change. As previously mentioned, models of health behavior often assume a relationship between perceived susceptibility and behavior.[1–6] It follows from this assumption that increases in perceived risk should be related to risk-reducing behaviors. To address this issue,

TABLE 4—Results of Multiple Regressions on Variables Related to Perceived Heart Attack Risk at Follow-Up

Variables	Unstandardized Regression Coefficient	S.E.
Baseline Risk Perception	.56	.04
Risk Factors		
Cholesterol relative to average	−.12	.04
Cigarettes smoked per day	.01	.002

[a]Scored relative to baseline perception of risk.

we looked at behavior change from baseline to follow-up as a function of change in risk perception. The behaviors we analyzed were: smoking, exercise, weight; self-reports of reduction in salt, fat, and calories; and recent blood pressure or cholesterol screening. Results showed that those who increased their perceived risk of a heart attack were no more likely to change their behavior than those whose risk perception either decreased or remained the same.*

Discussion

Our results showed that people do use established epidemiologic risk factors in estimating their overall risk of heart attack, but that additional factors also influence a person's risk perception. One such variable is self-perceived health status: those people who perceive their overall health as worse are more likely to rate their risk as higher. This finding is consistent with other research in which people who were sick estimated their risk for other illnesses as higher.**

Using an objective measure of individual risk, a high percentage of respondents exhibited an optimistic bias, providing additional support for previous studies.[9,10,13–16] Those who were younger and less educated tended to be more optimistic, consistent with suggestions that younger people feel less vulnerable to conditions or diseases.[16] The finding that family history of heart disease is associated with pessimism suggests that people weigh this factor heavily and is consistent with Becker and Levine's[8] study of high risk siblings of patients with coronary heart disease that found less optimistic bias than seen in other studies.

The effect of health risk feedback on risk perceptions was greatest for those who were above average in risk: twice the percentage of respondents who were above average risk *increased* their perceived risk. These findings suggest that HRA feedback can effectively change the perceptions of those at high risk. It is important, however, to add a cautionary note: 12 percent of those who received high risk feedback actually *decreased* their perceived risk and this above average group was the *least* accurate to begin with. Furthermore, the results of the multiple regression showed that only feedback from the AHT was significantly associated with change in risk perception. Clearly, feedback did not always have consistent effects on risk perception and these effects differed by HRA.

With respect to various explanations of the optimistic bias, to the extent that feedback had the desired effect on accuracy, the cognitive explanation of this bias is supported. However, it is also clear that information did not have the desired effect for the majority of respondents.

In the present study we did not find a relation between increases in perceived risk and behavior change. Although some models of health behavior predict a relation between perceived susceptibility and behavior,[1–6] support for this association is strongest for disease prevention behaviors that do not require modification of health habits.[26] Our behavioral measures consisted of changes in personal health habits such as smoking, diet, exercise, and weight. Models of health behavior also suggest that factors other than cognitions (e.g., social support, social norms and self-efficacy) may be important in health habit modification.[3,26,27] It should be pointed out, however, that this analysis was based on limited statistical power as only 87 respondents increased their perceived risk.

Two important aspects of this study need to be pointed out. One is that the logistic model of actual risk is based on mortality from heart attack, while respondents were asked about their chances of *having* a heart attack or stroke. It is possible that they may have responded differently if asked about their chances of dying from a heart attack or stroke, although we feel it is unlikely the respondents made this distinction. The other important point has to do with HRA feedback. Respondents were only given the feedback provided by the HRA and did not receive any additional counseling or education, as is often done with HRAs. In some cases, respondents may not have understood the feedback.*** Thus, HRAs may not be effective for use in mass screenings, but may have a greater effect on risk perception when feedback is easier to understand, or when they are given in conjunction with a health education program, a conclusion also drawn by Schoenbach, *et al*,[28] in a review of the effectiveness of HRAs.

In conclusion, this study suggests that people do make use of established risk factors in estimating cardiovascular risk; that compared to objective measures of risk, a high percentage of people display an optimistic bias; and that risk feedback has some effect on risk perception for those at high risk, but such feedback is not optimally effective.

NCHSR Grants $4 Million for Patient Outcome Research

The National Center for Health Services Research and Health Care Technology Assessment (NCHSR) has awarded new grants totaling nearly $4 million in first-year costs in a series that will measure the effectiveness of alternative medical procedures in treating specific health conditions. Total spending on the nationwide DHHS program will be $5.9 million this fiscal year, with $52 million proposed for FY 1990.

The new grants will support research for treatment of conditions that affect a large number of Americans every year—prostate gland enlargement, heart attack, cataracts, and lower back pain—for which millions of Medicare beneficiaries are treated every year. The research projects—expected to require about five years to complete—will assess comparative effects of alternative therapies on patient survival, quality of life, costs, and other factors. Research teams will consist of practicing clinicians and other experts.

Grants to support patient outcome research assessment teams were awarded to:

Richard Deyo, MD, University of Washington ($896,049), nonsurgical interventions for low back pain and different types of lumbar surgery;

Barbara J. McNeill, MD, Harvard Medical School ($900,000), for a national data base for outcomes from myocardial infarction treatment;

Earl P. Steinberg, MD, Johns Hopkins University ($899,986), assess cataract procedures;

John E. Wennberg, MD, Dartmouth Medical School ($933,535), transurethral resection, open prostate surgery, and nonsurgical interventions for enlargement of prostate gland.

Planning grants of $50,000 each awarded to seven research teams included:

Fred Featherstone, MD, American Academy of Orthopedic Surgery, hip replacement/disease; *Alvan Feinstein,* MD, Yale University, use of colonoscopy; *Emmett B. Keeler,* PhD, Rand Corporation, treating peripheral vascular diseases; *David B. Matchar,* MD, Duke University, prevention and management of stroke; *Lawrence W. McMahon, Jr.,* MD, University of Michigan, use rates and appropriateness of cholecystectomy, and screening/treatment for colon cancer; *David B. Pryor,* MD, coronary artery disease; and *Sanford Schwartz,* MD, University of Pennsylvania, gallstone disease.

The Prevention of Silicosis and Prediction of Its Future Prevalence in China

JIEZHI LOU, MD, AND CHEN ZHOU, MD, MPH

Abstract: We studied the effects of preventive and therapeutic interventions on the 18-year cumulative incidence of silicosis of 26,603 dust-exposed workers in seven Chinese mines and industrial plants. Cumulative silicosis incidence decreased from 36.1 percent in workers employed before 1950 to 1.5 percent in workers employed after 1960. From the 1950s to 1970s, eight-year cumulative incidence of tuberculosis decreased from 54.7 percent to 16.7 percent and case fatality of silicosis patients dropped from 53.9 percent to 18.3 percent. From 1950s to 1980s, the average age at the detection of silicosis increased from 41.3 to 52.7 and the average survival time of silicosis patients prolonged from 2.0 to 12.2 years. Workers over age 40 who began exposure to dust before 1960 will be the main source of new silicosis patients in future. Most expected new cases of silicosis will occur within the next 15 years. The silicosis population will remain unchanged for the next 20 years and will decrease dramatically after 25 years. There will be few silicosis patients in 30 years and new cases of silicosis will be difficult to find in 45 years. These results show that the preventive and therapeutic actions against silicosis in China have been effective. (*Am J Public Health* 1989; 79:1613–1616.)

Introduction

Silicosis is a major occupational lung disease which remains a problem in industrialized and developing countries.[1,2] Since the 1950s, special attention has been paid to the prevention of silicosis in China. A regulation to control the silica dust hazard in industrial establishments and mines was published in 1956,[3] and a regulation concerning the prevention and treatment of silicosis was published in 1957.[4] Experiences with dust control were summarized and applied nationwide in 1958. During the past 30 years, many industrial companies have implemented these regulations which include monitoring dust concentrations in the work environment, applying wet mining and engineering control methods, screening for silicosis in dust-exposed workers, and improving the care of silicosis patients. The evaluation of the effects of these preventive and therapeutic efforts on the change in prevalence of silicosis and predicting its future prevalence are important for future preventive programs.[5–7] We, therefore, conducted an investigation on the prevalence and development of silicosis in seven industrial companies of different types. Based on these data, we predicted the future trend of silicosis in these establishments.

Methods

Subjects and Their Industrial Environments

The subjects of this investigation had been exposed to dust for at least three years and had physical examination, occupational history records, and chest X-rays available for the study. The 26,603 dust-exposed workers came from two metallic mines (one lead mine, one molybdenum mine), two coal mines (coal mine 1, and coal mine 2), a fireproof raw material workshop in a steel plant, a foundry in a large machinery plant, and a raw material workshop in a glass factory. These seven industrial companies were selected as representative of different industrial environments with silica dust hazards and also because their records were complete.

Preventive and Therapeutic Interventions

From 1955 to 1957, the two metallic mines and two raw material workshops initiated comprehensive dust control programs focusing on wet operation. The other three establishments took similar actions in 1962 or 1963. Although there was no systematic dust monitoring data, the dust concentration were very high according to a few random measurements. After applying wet mining and engineering control methods, the average dust concentration decreased sharply (Table 1). Dust was collected on membrane filter and measured by gravimetric methods. Free silica content was measured by chemical-gravimetric method.

Silicosis patients were systematically screened and identified from the raw material workshops in 1950 and 1951 respectively. Similar screening in the two metallic mines—coal mine 2, and the foundry—began in 1955–56 and 1958–59, respectively, while the first screening for silicosis in coal mine 1 began in 1963. As the numbers of silicosis patients increased, the companies set up special physician-directed organizations to examine dust-exposed workers and to treat the silicosis patients. Dust-exposed workers were systematically screened annually and approximately one-third of the dust-exposed workers were examined by chest X-rays each year. More than 90 percent of the silicosis patients were

TABLE 1—Average Dust Concentrations (total dust) in Seven Industrial Companies before and after Dust Control Regulations

Companies	Date (years)	No. of Samples	Mean (mg/M^3)	SiO_2 (%)

transferred from jobs that exposed them to dust as well as given symptomatic treatment. Some companies also set up a special center to care for simple silicosis patients.

Diagnostic Criteria

The diagnosis of silicosis was performed by special silicosis diagnostic teams in each province or municipality. The criteria of radiographic classification of silicosis was based on the silicosis diagnostic criteria published by the Ministry of Health of People's Republic of China:[4]

> Stage I silicosis: definite evidence of nodular opacities. This demands at least 10 nodular opacities of 1 mm or larger in diameter in two square centimeters in any field of lung.
>
> Stage II silicosis: nodular opacities increase in number and enlarge in size and occupy more than four of the six lung fields.
>
> Stage III silicosis: nodular opacities conglomerate into large opacities of a minimum of 2 cm in diameter.
>
> Silicotuberculosis: tuberculosis developed in any stage of silicosis.

These criteria were set up for silicosis. They are crude and do not consider irregular opacities and profusion in comparison with ILO (International Labour Office) criteria, but they are accurate for silicosis diagnosis and easy to use.

If the subject was dead, the date of death, age at death, and cause of death were recorded. We interviewed the workers or their relatives and co-workers in a few cases when records were incomplete. We also recorded all workers who were no longer available because of non-silicosis related death or relocation.

Analysis

We divided the seven companies into three groups to represent three different industrial environments: metallic mines group (lead mine, molybdenum mine); coal mine group (coal mine 1 and coal mine 2); and plants group (a fireproof raw material workshop, a raw material workshop in a glass manufacturing factory, a foundry). We analyzed the prevalence of silicosis, case fatality rate, and causes of death among these three groups. To obtain the cumulative incidence rate, we divided observed workers into four cohorts according to the time of their first exposure to dust. The number of workers entered in these four cohort were 3,331, 7,108, 7,907 and 8,257, respectively, and the workers were followed up for 18 years, e.g., those with first exposure to dust before 1950 were followed up until 1966. A life table method was used to calculate the 18-year cumulative incidence of silicosis among workers who began exposure to dust before 1950, during 1950–54, 1955–59, and 1960–64.[8] The average annual incidence of silicosis was calculated as follows:

$$\text{average annual incidence (\%)} = \text{cumulative incidence (\%)/observed years.}$$

We also divided silicosis patients into three cohorts according to the time of diagnosis. Rates of silicosis progression, silicosis mortality and complication with tuberculosis in each eight-year diagnosis period.

To predict the future prevalence of silicosis, we used the average annual incidence rate derived from cumulative incidence of silicosis in dust-exposed workers, life expectancy of healthy dust-exposed workers of different age groups to predict the expected new cases of silicosis among healthy workers and the future trend of silicosis. The life expectancy of healthy dust-exposed workers of different age groups was calculated according to the life expectancy of male residents in Shenyang, China in 1976.[9] The details of this method were described in a previous report.[10]

Results

Silicosis

By the end of 1981, 3,803 silicosis patients were diagnosed (14.3 percent of the 26,603 dust-exposed workers). The rate in workers exposed to dust before 1950 was highest (36.1 percent), rates for workers employed later decreased gradually. For those who started employment in 1960 or later, the rates in the metallic mine group and the plant group decreased to 0.30 and 0.07 percent, respectively; the rates of the coal mine group remained somewhat high (3.0 percent) because of delay in dust suppression (Table 2).

The 18-year cumulative incidence of silicosis was highest in workers who started exposure to dust before 1950 and declined in those whose exposure started later (Table 3).

As the incidence of silicosis declined, the average age at disease occurrence and average duration from starting exposure to development of stage I silicosis (latent period) increased. The average age at which silicosis was diagnosed was 41.3 and average latent period 11.3 years in the 1950s, increasing to 45.7 and 14.5 in the 1960s, 48.7 and 17.0 in the 1970s, and 52.7 and 19.7 in the 1980s, respectively.

Disease Progression, Tuberculosis as a Complication

By the end of 1981, of the 3,803 diagnosed silicosis cases, 997 (26.2 percent) had progressed to a subsequent stage and 1,634 (43.0 percent) had been diagnosed as having tuberculosis. The average percent of progression (progressing from stage I to stage II and III or from stage II to stage III) was 26.2 percent and the average incidence of tuberculosis was 43.0 percent. Among the 1,634 cases of silicosis complicated with tuberculosis, 901 cases (55.1 percent) were identified at the time when silicosis was first diagnosed. The life table method was used to calculate the cumulative incidence of progression and of tuberculosis among patients diagnosed before 1955, in 1955–64 and in 1965–74 (Figures 1 and 2).

Death from Silicosis

By the end of 1981, 1,094 of 3,803 silicosis patients had died, a mortality rate of 28.8 percent. Figure 3 shows the case fatality within equal periods of eight years of the patients diagnosed in different time periods. The case fatality declined over time. Table 4 presents the average age at death and mean duration from silicosis diagnosis to death among three groups during different time periods. The average age at death and mean duration from diagnosis to death increased significantly over time.

TABLE 2—Cases of Silicosis among Workers Employed in Different Time Periods

	1970–	580	54.2	8.2
	1980–	185	58.0	12.2

The distribution of specific causes of death of silicosis patients is shown in Table 5. Tuberculosis was a major cause of death (62.1 percent). After improvement in health care, the proportion of death caused by tuberculosis dropped from 98.1 percent in the 1950s to 48.7 percent in the 1980s. With the increase in the mean age at death, the proportion of other pulmonary diseases, cardiovascular diseases, and cancer as causes of death increased from 1.9 percent in 1950s to 44.7 percent in 1980s.

Predicting New Cases of Silicosis

Using annual incidence rates of silicosis in dust-exposed workers, age distribution, and life expectancy of healthy dust-exposed workers, we calculated the expected number of cases of silicosis in the future (Tables 6 and 7). We estimate 464 new cases of silicosis are predicted to develop in the remaining 8,146 healthy workers in the metallic mine group, 1,412 cases are predicted to occur in 10,284 healthy coal miners and 248 cases in 2,520 healthy workers in the plant group. Workers over age 40 who started their exposure to dust before 1960 will be the main source of new cases of silicosis. Most expected cases of silicosis will occur within the next 15 years. The development of new cases of silicosis will be less after 35 years and will not be found in 45 years.

dust concentrations in the industrial environment were very high. In the seven establishments we studied, total dust concentrations were between 200 and 300 mg/M^3. The prevalence of silicosis under these high concentrations was about 36 percent, the latent period was 11.3 years, and patients died within two years after diagnosis. But since the Chinese government set up the regulations concerning the control of silica dust and prevention and treatment of silicosis in 1956 and 1957, all of these companies have made special efforts to prevent silicosis. Compared with the 1950s, the cumulative incidence of silicosis, incidence of tuberculosis in silicosis patients, and case fatality rate all declined dramatically. The average age at silicosis occurrence and survival time of silicosis patients increased significantly. These changes strongly demonstrated the effectiveness of preventive and therapeutic efforts in these companies. These silicosis prevention experiences could provide a valuable reference for rapidly industrializing countries.

Our results demonstrated that the prevalence of silicosis in dust-exposed workers decreased with improved working conditions and abatement of the dust concentration. In the coal mines, where dust level had not been completely controlled under the maximum allowable concentration, the prevalence of silicosis in workers employed after 1960 was still relatively higher than in other companies which had lower dust concentrations. Further action to suppress dust in these mines is necessary.

Recently, many researchers paid much attention to predicting epidemiological trends of silicosis incidence.[6,7,10] Since many factors could affect silicosis incidence, it is difficult to estimate the trends accurately. The life table method we used here is a simple but effective approach. With the average annual incidence rate derived from the cumulative incidence of silicosis, the age distribution and life expectancy data of healthy dust-exposed workers, new cases of silicosis could be estimated accurately.

In this study, we found that the workers age 40 and older who were exposed to dust before 1960 will be the major source of new silicosis patients. This result is consistent with those of two investigations reported by Lou, *et al.*[10,11] The future preventive work in these companies should concentrate on early detection of silicosis among these older workers and delay the development of the disease.

Since this investigation was done in 1985 and most new cases of silicosis will develop in the next 15 years, the silicosis population will not decrease within this century. Also, because the survival time of silicosis is between 10 to 15 years, the silicosis patient population will decline sharply after 25 to 30 years. In the years 2020 or 2030 (35 or 45 years later), new cases of silicosis will be very difficult to find. These predictions show that silicosis will remain a problem for the next 40 years, therefore, it is also necessary to improve health care delivery for silicosis patients and develop new anti-silicosis drugs or therapies to prolong their life expectancy.

Risk of Carotid Endarterectomy in the Elderly

ELLIOTT S. FISHER, MD, MPH, DAVID J. MALENKA, MD, NEIL A. SOLOMON, BA, THOMAS A. BUBOLZ, PHD, FREDERICK S. WHALEY, PHD, AND JOHN E. WENNBERG, MD, MPH

Abstract: We used the Medicare claims files to describe operative mortality for 2,089 New England residents over the age of 65 who underwent carotid endarterectomy in 1984 and 1985. For patients ages 65 to 69, the risk of death within 30 days of surgery was 1.1 percent, (95% confidence interval = 0.5, 2.1), for those ages 70 to 74, 2.8 percent (1.7, 4.4), for those ages 75 to 79, 3.2 percent (1.8, 5.2), and for those over age 80, 4.7 percent (2.3, 8.5). Nearly 80 percent of patients underwent surgery at hospitals performing 40 or fewer carotid endarterectomies per year on the Medicare population. The adjusted odds ratio for 30 day mortality for patients undergoing surgery in these low-volume hospitals was 2.8 (95% CI = 1.1, 7.2) compared to higher volume hospitals. Although the Medicare claims data provided only limited data about post-operative strokes, analysis of post-operative stroke risk supported these findings. (*Am J Public Health* 1989; 79:1617–1620.)

Introduction

Carotid endarterectomy is commonly performed, costly and controversial. In 1985, more than 100,000 operations were performed in the United States at a cost of $1.2 billion.[1,2] While the operation may reduce the risk of stroke compared to medical management, the currently available scientific evidence is insufficient either to reject or endorse this hypothesis.[2–5] Only two randomized trials on this question have been completed, each with inconclusive results.[6,7] Clinical uncertainly about the appropriate indications for the procedure is reflected in the high degree of regional variation in the utilization rates of carotid endarterectomy.[8,9] For example, residents of Boston, Massachusetts are twice as likely to undergo carotid endarterectomy as residents of New Haven, Connecticut.[10]

The potential benefit of the operation depends primarily on the operative mortality and the risk of stroke with medical or surgical management and high post-operative complication rates virtually eliminate the potential benefit of the operation for all patient subgroups.[3,11,12] Many argue that carotid endarterectomy should be restricted to specialized centers[13,14] or to those with documented operative stroke plus death rates under 5 or 6 percent.[15]

Published case series demonstrate wide variation in complication rates, with stroke plus death rates ranging from 3 percent to over 15 percent.[9,16–19] Three small studies found no significant increased risk in patients over the ages of 75 or 80 and advocated the use of the procedure in elderly patients.[20–22] Low surgical volume has been found to be associated with increased risk for many surgical procedures. Carotid endarterectomy has been specifically examined in two studies, neither of which found an effect of surgical volume on outcome. However, the statistical power of these two studies was limited, as was the spectrum of institutions included in their analyses.[23,24]

We used the Medicare claims files for the six New England states to address three issues: the effect of age on the operative risk of carotid endarterectomy, the association of low surgical volume with increased risk, and the evaluation of the performance of carotid endarterectomy at individual hospitals.

Methods

Data Source

Data for the current study were obtained from three computer files maintained by the Health Care Financing Administration:[25]

- the Medicare Provider Analysis and Review (MEDPAR) file, which contains computerized discharge abstracts for each hospitalization for Medicare enrollees and includes patient and hospital identifiers and data on diagnoses, procedures, and resource utilization;
- the Health Insurance Skeletonized Eligibility Writeoff (HISKEW) file which records whether a patient died and the date of death, regardless of whether that death occurred within a hospital; and
- the Provider of Services file, which describes the relevant characteristics of all Medicare institutional providers.

Selection of the Study Population

We reviewed all 2,171 hospital discharge abstracts submitted for New England resident Medicare beneficiaries 65 years of age and older discharged between April 1, 1984 and June 30, 1985 who underwent carotid endarterectomy (ICD-9-CM procedure code 38.12). After eliminating the 81 patients who received surgery outside New England and one patient with inconsistent coding, 2,089 patients were selected for inclusion in the study. If the endarterectomy was not listed as the primary procedure (n = 83, 3.8 percent of cases), we assigned the date of surgery for the index endarterectomy to the midpoint of the hospital stay. (We repeated all reported analyses using the date of admission as the date of surgery for these 83 cases; none of the analyses were affected.)

Outcomes

Deaths were determined by searching the write-off file. Stroke was ascertained by inference from the diagnostic codes recorded on the discharge abstract for the index admission and readmissions within 30 days of surgery. If patients' diagnosis codes could be consistent only with a post-operative stroke (n = 35), they were coded as having definite post operative strokes. If the coding of the stroke was ambiguous and thus might have represented a pre-operative stroke, the patient was coded as having a possible stroke (n = 161).* Based on these definitions, we calculated the

proportion of patients who experienced the following outcomes within 30 days of surgery: death; death or definite post-operative stroke (the minimum estimate of the stroke plus death risk); death or any possible post-operative stroke, which represents the maximum risk of death plus stroke that can be ascertained from the discharge abstract (some additional strokes might be detected through chart review). Confidence intervals for these proportions were calculated according to the exact method.[26]

Independent Variables

Patients' age, sex ,and race were ascertained from the discharge record. To identify important medical conditions of patients, we used diagnostic codes from both the surgical (index) admission and from any admissions whose discharge date fell within the six months preceding the date of the index surgical procedure, as previously described.[27] If an index admission diagnosis could reasonably be interpreted as a potential complication of the endarterectomy, a patient was coded as having that condition only if it was also present on admissions that preceded the one in which the endarterectomy occurred. Variables evaluated as risk factors for adverse outcomes were: coronary artery disease, pulmonary disease, diabetes, renal disease, congestive heart failure, valvular heart disease, stroke, and the presence of any hospital admission during the previous six months.

Hospital surgical volume was defined based on the number of index carotid endarterectomies performed by each hospital on the Medicare population during the 15-month study period. Institutional size was defined as a continuous variable based on the number of hospital beds. Hospital teaching status was defined as a continuous variable based on the number of housestaff in accredited residency programs per hospital bed.

Analysis

We used multiple logistic regression to test the association between each of the three outcomes and the clinical and institutional predictors described above.[28] Of the clinical variables considered, only coronary artery disease was significantly associated with 30-day mortality after controlling for age, sex, and surgical volume. Both sex and coronary artery disease were included in the reported logistic regression models. Alternative specifications of the model, in which teaching status and hospital size were treated as both dichotomous and ordinal variables, were examined. Regardless of the specification of the model, the results were similar to those presented below. Two-way interactions between surgical volume and age, and age and sex were examined and were not significant.

We used the binomial distribution to test the hypothesis that the observed number of deaths plus definite strokes at an individual hospital exceeded the number that would have been expected had the hospital's outcomes equaled those of the highest volume hospitals.

Results

Operative Mortality

Operative mortality increased markedly with age (Table 1). Those over age 70 faced a progressively increased risk, with those over age 80 facing a more than four-fold increase in the adjusted odds of death compared to those ages 65 to 69. Operative risk was also higher in hospitals with low surgical volume on the Medicare population (Table 1). Patients undergoing carotid endarterectomy in hospitals in each of the three lower volume groups faced an increased risk of death compared to those receiving surgery in hospitals performing more than 40 endarterectomies per year. The increased risk associated with low-volume surgery was consistent across all specifications of the model examined. When a dichotomous variable was substituted for the three levels of lower hospital volume in an otherwise identical model, the adjusted odds ratio for 30-day mortality at hospitals performing 40 or fewer endarterectomies per year compared to higher volume hospitals was 2.83 (95% CI = 1.11, 7.19). When volume is treated as a continuous variable in the same model it is also significant ($p = .03$), and remains so after controlling for teaching status and hospital size.

TABLE 1—Death within 30 Days of Carotid Endarterectomy, Adjusted Odds Ratio and Risk by Patient Subgroup

Patient Age (years)	(N)	Adjusted Odds Ratio* (95% CI)	% Risk (95% CI)
65–69	(733)	1.00	1.1 (0.5, 2.1)
70–74	(671)	2.58 (1.12, 5.95)	2.8 (1.7, 4.4)

*Derived from multiple logistic regression with age, sex, surgical volume, and presence or absence of coronary artery disease as covariables. The first level of each category is the reference.

**Volume defined as the number of carotid endarterectomies performed per year on the Medicare population at each hospital.

Risk of Death or Stroke

Because we were unable to characterize the timing in relation to surgery of the majority of strokes recorded on the discharge abstract, we present both a minimum and maximum estimate of post-operative death plus stoke risk in Table 2. Regardless of the definition used, the risk of death or stroke increases significantly with age and at lower volume hospitals.

Individual Hospital Outcomes

We identified all hospitals where the number of observed deaths or definite strokes was greater than what would have been expected ($p < .10$), using as the standard of comparison the outcome rate in those hospitals performing more than 40 carotid endarterectomies per year (Table 3). Twenty-two of the 139 New England hospitals performing endarterectomy were found to have high complication rates compared to high volume hospitals. Only seven New England hospitals performed more than 40 carotid endarterectomies per year on the Medicare population, while 50 hospitals performed five or fewer.

Discussion

Several authors have found no increase in operative mortality in the elderly and have argued that age should not be a consideration when choosing endarterectomy.[21–23] In

TABLE 2—Death or Stroke within 30 Days of Carotid Endarterectomy Adjusted Odds Ratios (AOR)* and Risk by Patient Subgroup

		Death or Definite Stroke		Death or Possible Stroke	
Patient Age (years)	(N)	AOR (95% CI)	% Risk (95% CI)	AOR (95% CI)	% Risk (95% CI)

6 to 20	65	10
21 to 40	17	6
Over 40	7	0
Total	139	22

*For each hospital, the expected proportion of definite strokes plus deaths is assumed to be .0197, the proportion that occurred in the high-volume hospitals. Given this proportion, the probability that a hospital would have at least as many strokes plus deaths as actually reported is computed. A hospital where this probability is .10 or less is considered to have a significantly high rate. The number of definite strokes plus deaths is assumed to have a binomial distribution.

contrast, our study demonstrates a markedly increased mortality risk with increasing age. Two-thirds of the New England Medicare patients undergoing endarterectomy were over the age of 70 and faced an average three-fold increased risk of operative death compared to younger patients. Patients undergoing surgery at low-volume hospitals also faced a three-fold increased risk of death compared to those receiving surgery at high-volume hospitals.

Our analyses of post-operative stroke risk are consistent with the findings of our mortality analyses, but leave uncertainty about the actual risk of non-fatal stroke following endarterectomy. Several lines of evidence suggest that the actual risk is considerably higher than our minimum estimate of death plus stroke risk (4.2 percent). First, a population-based sample of Medicare patients undergoing carotid endarterectomy in 1981 were found to have death plus stroke risks of 9.8 percent overall, based on review of hospital records.[29] Second, each of the five recent series that described the outcomes of carotid endarterectomy across multiple hospitals report a ratio of non-fatal strokes to deaths of approximately two-to-one.[23,29–32] Applying this ratio to our data would suggest a stroke plus death risk of 7.5 percent overall, high enough to raise serious questions about the relative risks and benefits of endarterectomy in the elderly.[29]

A potential criticism of our findings is that the data on disease coded in discharge abstracts may not provide sufficient information to adequately control for severity of illness and comorbidity.[33] Although we share this concern,[27] particularly with respect to the comparison of aggregate hospital mortality rates, the limitations of the diagnostic coding should not undermine our current analysis. It is clear from both the Rand consensus panel's conclusions[12] and from decision analysis[11] that high post-operative complication rates virtually eliminate the potential benefit of the operation for all patient subgroups, no matter what assumptions are made about the operation's efficacy or the stroke rate among medically managed patients. Thus patients who undergo surgery at hospitals which experience high rates of post-operative morbidity and mortality are unlikely to benefit from the surgery, regardless of whether the high rate is due to patient selection or to poor technical performance of the procedure itself. In fact, severity adjustment could obscure important differences in outcomes across institutions due to what may be inappropriate patient selection.

Given the current uncertainty about the value of carotid endarterectomy, the importance of operative risk to the expected benefit of the procedure and the wide variation in post-operative complication rates at individual hospitals, patients and their physicians should seek reliable data on the operative risk of death and stroke at the hospital where the operation is to be performed. These data are currently unavailable. One solution would be for individual hospitals to review their records and report their results. Such a moni-

toring program would be limited by the degree to which hospitals could ascertain post-discharge events and by concern about the potential conflict of interest for hospitals collecting and reporting the data.

Our study suggests a practical alternative for the 70 percent of patients undergoing endarterectomy who are over the age of 65[1] and thus eligible for Medicare. Data in the claims files could be used to establish an ongoing monitoring program that would identify all patients undergoing endarterectomy and ascertain post-operative mortality. Chart reviews could be carried out to ascertain post-operative stroke rates and accurately classify patients' severity of illness and comorbidity. Accurate risk stratification, whether by age or clinical indications or both, would improve hospital comparisons and enhance individual clinical decision-making. The effort required to establish such a monitoring program would be far less than that required to establish an independent prospective data collection system to provide patients and physicians with accurate information on institution-specific operative risks.

One limitation of any monitoring program is that hospitals where few operations are performed cannot be reliably evaluated; small numbers make it impossible to distinguish the few with excellent outcomes from those with worse than average performance.[34] Given the importance of a low complication rate to the potential benefit of carotid endarterectomy, the difficulty of evaluating low volume hospitals' outcomes and the demonstrated volume-outcome association, it may be reasonable to restrict carotid artery surgery to high volume hospitals that demonstrate excellent outcomes.

The controversy surrounding carotid endarterectomy has been heightened by recent reports confirming that a significant proportion of the carotid endarterectomies performed in the United States are carried out in clinical settings where experts believe the risk outweighs the potential benefit.[11,29] Our findings of increased risk in the elderly and at low-volume hospitals are consistent with this conclusion. An ethical solution to the controversy would be to provide patients with the best available information on the potential benefits and risks of alternative treatments so that the decision may reflect their values.[34] The Medicare claims files, supplemented as necessary with chart review, provide a readily available and feasible method to improve the quality of information available to patients and their physicians.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. Robert Greenberg and Dr. Harold Sox for their helpful suggestions on an earlier draft. The substance of the paper was presented previously at the Robert Wood Johnson Clinical Scholars Program annual meeting in October 1988 and appeared as an abstract in *Clinical Research*, April 1988. Geographic Variation in the Onset of Decline of Male Ischemic Heart Disease Mortality in the Netherlands

JOHAN P. MACKENBACH, MD, PHD, CASPAR W. N. LOOMAN, MSC, AND ANTON E. KUNST, MSC

Abstract: We studied variation in the year of onset of ischemic heart disease mortality decline among regions (n = 39) in the Netherlands. Using loglinear regression methods, a quadratic regression model was fitted to the observed numbers of male deaths in each region in the period 1950–84, controlling for changes in age-structure of populations. The quadratic regression model proved inadequate to describe the mortality experience of females.

For the country as a whole, the estimated year of onset of male ischemic heart disease mortality decline is 1973.9. The difference between the earliest and the latest region is almost nine years (1970.0 and 1978.9, respectively). An early onset of decline (≤1972) is only found in the urbanized, western part of the country. A later (≥1975) onset of decline is characteristically found in more peripheral regions in the South-West and South-East, as well as in the North.

Exploratory correlation and regression analyses show that both average income and percent of population living in larger cities have independent, negative associations with the year of onset of male ischemic heart disease mortality decline.

We argue that regional variation in the timing of lifestyle changes is a more plausible explanation of these observations than regional variation in the timing of medical care improvements. (*Am J Public Health* 1989; 79:1621–1627.)

Introduction

After more than 30 years of rising death rates from ischemic heart disease, a dramatic decline has occurred in many industrialized countries, with large differences in the year of onset of decline.[1]

In the United States, the mortality rates plateaued in the early 1960s, and had definitely started to decline in 1968.[2–4] In Australia, death rates from ischemic heart disease reached their highest levels in 1965–67,[5] and in New Zealand in 1968.[6]

In Europe, the decline started in the first half of the 1970s in Denmark, Norway, Finland, the Federal Republic of Germany, Belgium, the Netherlands, and England and Wales. On the other hand, in Ireland, France, Switzerland, Austria, Italy, and Sweden, ischemic heart disease mortality started to decline in the second half of the 1970s. In most Eastern European countries, including Hungary, Poland and Romania, mortality rates were still increasing at that time.[1]

These international differences suggest a process of gradual and worldwide diffusion of the factors responsible for ischemic heart disease mortality decline: from a focus in the New World (including Australia and New Zealand) to Europe, and within Europe from West to East.

Such a process of gradual diffusion has also been found within the United States. Two studies of geographic variation in the year of onset of ischemic heart disease mortality decline within the United States have been reported, showing a considerable range of variation between State Economic Areas[7] and States,[8] respectively. Early declines were reported for California[9,10] and New York.[11] In general, metropolitan areas had earlier years of onset of decline than non-metropolitan areas, suggesting that the factors responsible for the mortality trend reversal have spread across the population according to a general pattern of cultural diffusion.[7]

In the Netherlands, age-standardized mortality from ischemic heart disease reached its highest level in 1972, for both males and females (Figure 1).

Among males, ischemic heart disease death rates more than doubled from 105 per 100,000 person-years in 1950, to 236 per 100,000 person-years in 1972. Thereafter, a gradual

decline set in, with a secondary peak in 1976, to a rate of 191 per 100,000 person-years in 1984. Among females, the increase between 1950 and 1972 was much less steep than in males, but the decrease after 1972 was almost as rapid.

The causes of this trend reversal have not been extensively investigated in the Netherlands. There is some evidence for a reduction of serum cholesterol between 1960 and 1979.[12,13] The prevalence of self-reported smoking (but not the number of cigarettes sold per capita) has been declining since 1958 in males and since 1970 in females.[14,15] There is no information on trends in the prevalence or the detection and treatment of hypertension in the Netherlands. Changes in the medical management of patients with ischemic heart disease have probably mirrored those in other industrialized countries, but quantitative information on trends at the national level is not available.

The objective of our study of regional variation in the year of onset of mortality decline is to provide some clues to the causes of the mortality trend reversal for ischemic heart disease: if a pattern of geographical variation has been identified, it will be easier to find the factors responsible for the trend reversal, because these must have followed the same pattern. Because of estimation problems in females, we will report only on variation in the year of onset of decline in males.

Methods

Numbers of deaths by age (<1, 1–4, 5–14, ... 85–94, 95+ years), sex, calendar-year (1950–84), region, and four-digit-number of the International Classification of Diseases (ICD) were available from a large computer file supplied by the Netherlands Central Bureau of Statistics.

For statistical purposes, the Netherlands have been divided into 40 regions, each representing a geographical area serviced by one or more larger cities (Figure 2). Total population of the Netherlands was 14.4 million in 1984; the median population size of these 40 regions was approximately 300,000 in 1984.

The economic and cultural center of the country is located in the largely urbanized quadrangle bordered by the regions containing the four largest cities of Amsterdam, The Hague, Rotterdam, and Utrecht. In the rest of the country, a number of secondary centers is found (indicated in Figure 2, which shows the location of other cities with more than 100,000 inhabitants), with other regions occupying a more "peripheral" position, from both a geographic and a cultural point of view. Region no. 40, land which was recently claimed from the waters of the former Zuiderzee, was excluded from the analysis because its population was very small before the end of the 1970s.

For ischemic heart disease, ICD-revisions 6 and 7, we included 420 (arteriosclerotic heart disease) and 422.1 (other myocardial degeneration with arteriosclerosis). The latter number was included because bridge-coding between revisions 7 and 8 revealed that this category was transferred to the ischemic heart disease-section in ICD-revision 8, 410-414.[16] For ICD-revision 9 we included 410-414 (ischemic heart disease) and 429.2 (cardiovascular disease, unspecified), the latter because bridge-coding between revisions 8 and 9 showed that its separation from ischemic heart disease in revision 9 was the main factor behind the lower-than-1 comparability ratio.[17] As Figure 1 shows, the mortality trend shows no signs of sudden changes at the moments of introduction of new ICD-revisions (1969 for ICD-8, and 1979 for ICD-9), suggesting that comparability over time of our cause-of-death category "ischemic heart disease" is satisfactory.

FIGURE 2—Map of the Netherlands, Showing Division into 40 Statistical Regions and Location of Cities with More than 100,000 Inhabitants

Higher age-groups were not excluded from the analysis, because declines in ischemic heart disease mortality have occurred at all ages, and have even been remarkably uniform in the Netherlands.[18]

Population numbers by age, sex, calendar-year, and region were available from several sources based upon the Dutch population register which is kept up to date continuously. Approximate person-years at risk for the deaths occurring in a given calendar-year were calculated by averaging the population numbers for December 31 of both the current and previous years.

Loglinear regression analysis was used to obtain estimates for the years of onset of decline of ischemic heart disease mortality. We chose the loglinear model because our dependent variable is a person-time rate. The model was fit by assuming a Poisson distribution for the number of cases observed. For each region a quadratic regression equation was fit to the observed number of deaths with the following structure:

$$E(y_i) = N_i e^{\alpha_i + \alpha + \beta_1 X + \beta_2 X^2}$$

in which:

- $E(y)$ = expected number of deaths
- N = person-years at risk
- e = base of natural logarithm
- α = national mortality level, 1950
- α' = regional departure from national mortality level, 1950
- β_1, β_2 = regional mortality trend parameters

X = calendar-year
i = subscript denoting age-group.

We used national mortality levels by age (α_i) to adjust the regional trend parameters for changes in age-composition of the population. From β_1 and β_2 the year of maximum mortality rates, marking the onset of decline, can easily be calculated. The variance and covariance estimates of β_1 and β_2 from the regression calculations and a Taylor series expansion[19] were used to obtain variance estimates for the years of maximum mortality. An approximate asymmetric 95 percent confidence interval was derived with the help of Fieller's theorem.[20] The calculations were performed with the GLIM-package.[21]

In order to test the goodness-of-fit of our quadratic regression model, we inspected plots of observed and expected (under the model) numbers of deaths and performed a Wald-Wolfowitz "runs test" on the residuals.[22] Both methods suggested a considerably better fit in males than in females.

In males, the estimated years of onset of mortality decline closely correspond to what one would guess on the basis of visual inspection. At the national level, for example, the estimate is 1973.90, slightly later than 1972 due to the secondary peak in 1976, but still a satisfactory measure. In females, however, the estimated years of onset are considerably earlier than 1972, due to the flat rise and steep decline of the curve (Figure 1). At the national level the estimate is 1969.03.

The "runs test" identified only two regions with statistically significant ($p < .05$) deviations from a quadratic model in males (to be expected from chance alone), but four in females. In these cases, fitting higher order polynomials produced more satisfactory fits, but did not change the estimated year of onset of decline in males. In females, however, it produced very different estimates, suggesting that the quadratic regression model is really inadequate. For these reasons we decided to restrict this presentation to the results obtained for males.

The national number of deaths from ischemic heart disease among males over the entire period 1950–84 was 412,613. Regional numbers varied from 1,744 to 41,785, with 8,121 deaths in the region with the median population size.

Results

The estimated years of maximum male mortality from ischemic heart disease, marking the year of onset of mortality decline, are presented in the appendix, together with their 95% confidence intervals. Even in a small country like the Netherlands, the difference between the earliest and the latest region is almost nine years: the range of variation is from 1970.0 to 1978.9. Although confidence intervals are sometimes wide, especially for smaller regions, there is no overlap between the confidence intervals for regions with an early onset of decline (≤1972) and those with a late onset of decline (≥1977).

There appears to be a bimodal frequency distribution of the year of onset of decline of ischemic heart disease mortality among males in Dutch regions (Figure 3). The first peak in the distribution represents 17 regions (containing 50 percent of the Dutch male population) with an estimated year of onset of decline in 1973 or 1974, i.e., corresponding to the national average. Only six regions (containing 26 percent of the Dutch male population) had years of onset of decline before 1973. After 1974, a smaller second peak in the

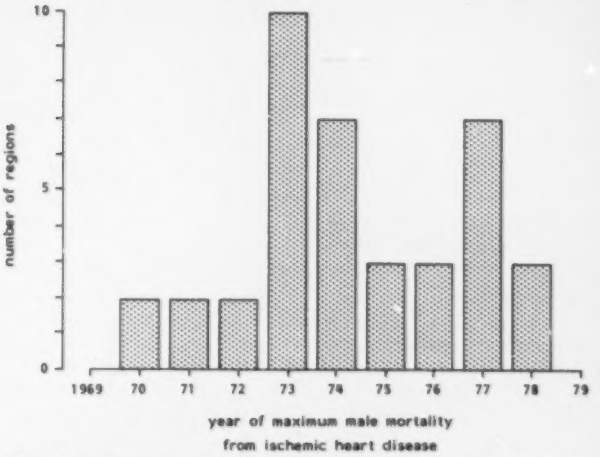

FIGURE 3—Frequency Distribution of the Year of Maximum Male Mortality from Ischemic Heart Disease, 39 Regions, the Netherlands

frequency distribution appears in 1977. This second peak may partly explain the second peak in the national mortality trend in 1976 (Figure 1), although the years do not exactly correspond.

Figure 4 illustrates the spatial distribution of the year of

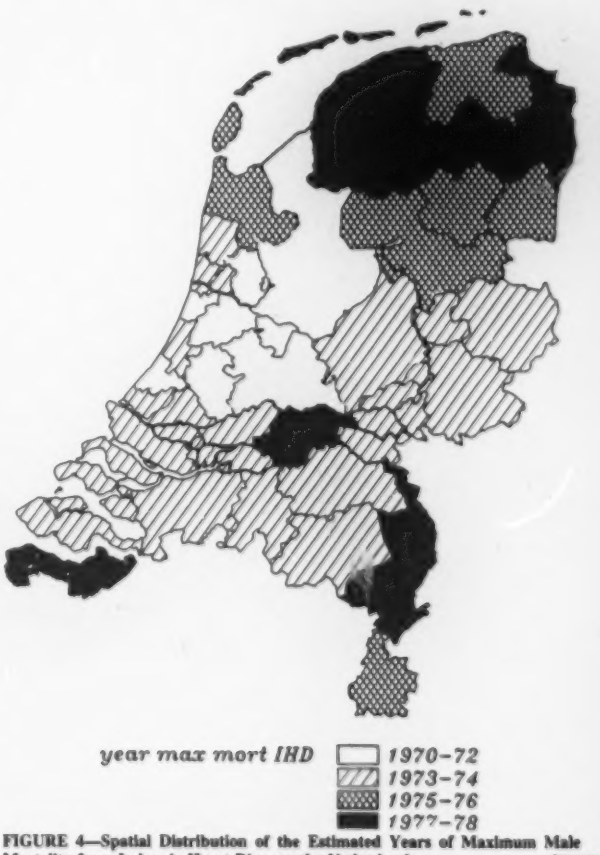

FIGURE 4—Spatial Distribution of the Estimated Years of Maximum Male Mortality from Ischemic Heart Disease, the Netherlands

onset of decline of ischemic heart disease mortality among males in the Netherlands.

An early onset of decline (≤1972) is only found in a number of regions located in the urbanized, western part of the country, including the regions containing Amsterdam and the Hague, but not the region containing Rotterdam. A later (≥1975) or late (≥1977) onset of decline are characteristically found in more peripheral regions in the South-West and South-East, as well as in the North. There is only one exception: region no. 16, very centrally located from a purely geographical point of view but rural in character, had its year of onset of mortality decline in 1977.

Regional differences in the year of onset of mortality decline represent important differences in the timing of the ischemic heart disease mortality "epidemic" as a whole. Figure 5 shows two "cross-sectional" views of ischemic heart disease mortality among males, for the early 1950s and early 1980s, respectively. In 1980–84, the regions in the highest quintile of the distribution were mainly located in the North and South-East, parts of the country which were also characterized by a late onset of mortality decline.

This pattern gradually emerged from a completely different pattern of variation in the early 1950s, when areas with higher than average mortality were mainly found in the West. (The product-moment correlations between year of onset of decline and mortality levels in 1980–84 and 1950–54 were 0.69 and −0.48, respectively.) This suggests that the epidemic of ischemic heart disease mortality started and ended earlier in the western parts of the Netherlands.

In an exploratory search for covariates of regional differences in the year of onset of male ischemic heart disease mortality decline we calculated product-moment correlation coefficients with a number of sociodemographic variables, all measured in a year close to (mostly just before) 1973 (Table 1).

The correlations confirm the impression that lower values of year of onset of decline are found in more urbanized areas: the correlation coefficient with percentage population living in larger cities is 0.74. On the other hand, the year of onset of decline also appears to be strongly associated with socioeconomic characteristics: lower average income goes together with a later onset of mortality decline.

Two variables measuring another important cultural division, percentage population of protestant c.q. roman-catholic religious affiliation, usually powerful predictors of mortality patterns in the Netherlands, are not associated with the year of onset of ischemic heart disease mortality decline.

The results of a multiple regression analysis (Table 2) show that both average income and percentage living in larger cities have an independent, negative association with year of onset of decline. After controlling for these two powerful predictors two additional socioeconomic variables appear to be associated with

the year of onset of decline: percentage working in industry (negative association) and percentage unemployed (positive association). The percentage of variance explained by these four variables is considerable, 77 percent.

Discussion

In their analysis of the onset of decline of ischemic heart disease mortality in the United States, Ragland and associates found a range of variation between States of almost 15 years for White males aged 55–64 years, from 1952.82 in California to 1967.29 in West Virginia.[8] If their units of analysis had been smaller, they would probably have found an even wider range of variation. This is evident from the study of State Economic Areas by Wing and associates, who found that 1.6 percent of these areas had a year of onset of decline as late as in or after 1973.[7] We feel that a range of variation of almost nine years between regions in such a small country as the Netherlands is no less dramatic.

Although differences in cause-of-death certification are a potential threat to the validity of all studies of geographical variation in cause-specific mortality, it is implausible that such differences could account for the variation in year of onset of decline of ischemic heart disease mortality observed in this study. As changes in certification have probably not contributed much to the trend reversal of ischemic heart disease mortality at the national level,[4] it is difficult to see how any regional differences in such changes could have produced such dramatic variation in year of onset of decline. Moreover, the validity of Dutch cause-of-death certification compares favorably with that of many other European countries.[23,24] Coding of death certificates is done centrally in the Netherlands.

Another potential threat to the validity of our study might arise from violations of the assumptions underlying the quadratic regression model (i.e., a unimodal distribution of mortality over time, and equal rates of increase before and decrease after the top-year). These assumptions were reasonably satisfied for males, however. Although the national mortality trend for males is bimodal (Figure 1), this appears to be the result, at least in part, of the superposition of two unimodal trends with a different timing (Figure 2). For females, the rate of increase before the early 1970s is much smaller than the rate of decrease thereafter, so that a quadratic regression model cannot be used to estimate years of maximum mortality. This is unfortunate, because a comparison of regional patterns for females with those for males could give important additional information. Further study of female ischemic heart disease mortality decline in the Netherlands, using an appropriate model form, is therefore to be recommended.

Despite a vast amount of literature, there is still no consensus on the relative contributions of changes in risk factor levels and improvements in medical care to the reduction of ischemic heart disease mortality.

A decline in incidence of myocardial infarction has been found in a number of population-based studies, both from the United States[25–27] and from a few other countries.[28–30] Lifestyle changes, leading to reduced tobacco consumption and lower serum cholesterol levels, have almost certainly contributed to this decline.[4,6,31,32]

Examinations of trends in myocardial infarction survival have produced a more diffuse picture than those of trends in incidence. Some studies have reported a decrease in in-hospital case fatality rates[26,27] but others have not done so.[33,34] Studies which have examined long-term survival reported no improvements.[26,35,36] (In most of these studies, the time-periods examined preceded widespread use of beta-blocking agents for long-term patient management.) Nevertheless, a recent comparison of two cohorts suggested that early detection and treatment did contribute to the observed decline in ischemic heart disease mortality.[37] Estimates of the contribution of specific medical interventions to the decline in the United States between 1968 and 1976 range as high as 40 percent.[32]

Although the pattern of international variation in onset of decline mentioned in the introduction could be consistent with a diffusion process of either lifestyle or medical care innovations, a detailed comparison of available data suggests that lifestyle factors are the better candidates.[38] Sweden is a particularly enlightening case because it combines a very advanced health care system with a late year of onset of decline of ischemic heart disease mortality.[39]

It is important to note that the spatial distribution of the year of onset of ischemic heart disease mortality decline within the Netherlands is analogous to that observed in the

United States.[7,8] In both countries the decline started in the highly urbanized areas which are regarded as the cultural center(s) of the nation, and gradually diffused to more "peripheral" regions. In the Netherlands, as in the United States, the factors responsible for the mortality trend reversal thus seem to have spread according to a general pattern of cultural diffusion. In the Netherlands, as in the United States,[40] socioeconomic factors seem to play an important role in this diffusion process. Theoretically, both changes in medical care (improved control of hypertension and/or better management of patients with cardiovascular disease) and changes in lifestyle could have spread according to such a pattern. For a number of reasons, however, we believe that differences in timing of lifestyle changes are a more plausible explanation for the Netherlands:

- If differences in timing of changes in medical care were to explain the regional variation in onset of decline of ischemic heart disease mortality, one would have to assume that the providers of medical care in the most "backward" regions adopted these improvements almost nine years later than those in the most "advanced" regions. In view of the short lines of communication within the Dutch medical care system, and of the geographically homogeneous insurance schemes, this seems a very unrealistic assumption. Diffusion of changes in lifestyle in the population at large, on the other hand, is probably a much slower process.
- If the degree of urbanization were an indicator of early diffusion of innovations in the medical care of ischemic heart disease, one would also expect an association between the presence of a university hospital, as a typically metropolitan and diffusion-prone institution, and the year of onset of mortality decline. In 1970, there were seven university hospitals in the Netherlands, all located in cities with 100,000+ population. The average year of onset of male ischemic heart disease mortality decline in regions with a university hospital was 1973.6, almost exactly the same as the national average. This is due to the fact that one university hospital is located in the North (region no. 3, with its year of onset of decline in 1976), and only three are located in regions with an early decline (one in no. 17 and two in no. 23, with their years of onset of decline in 1972 and 1971, respectively). Also after controlling for average income, there is no association between the percentage of hospital beds located in university hospitals and the year of onset of decline.
- The association between year of onset of decline and average income suggests that an early adoption of factors promoting ischemic heart disease mortality decline is not only determined by circumstances directly linked to living in large cities, but also to the more favorable socioeconomic circumstances prevailing in the western parts of the country. This suggestion is supported by the results of analyses at the individual level from England and Wales, which have shown that ischemic heart disease mortality decline started earlier in higher socioeconomic groups.[41] In England and Wales, this variation corresponds to differing trends in lifestyle related risk factors such as smoking and high cholesterol intake.[42] In the Netherlands, too, the decline in smoking among males started in the higher socioeconomic groups.[14]

International Study Program on Alcohol/Drug Abuse Prevention and Education

WHO: Health Professionals in the Alcohol/Drug Abuse Prevention Field, Teachers/Counselors/Administrators

WHAT: Graduate Overseas Summer Study Opportunities "Alcohol and Other Drug Education and Abuse Prevention Programs"

WHEN: June 11–25, 1990

WHERE: Stockholm, Sweden

CO-SPONSORS: People to People International, University of Missouri-Kansas City

COURSE: 3 Credit Hours; CEUs available

Alcoholism and other drug abuse is an international problem which professionals in every nation are addressing through creative prevention and treatment measures. This international study opportunity in Stockholm, Sweden will feature government officials, educators, health professionals, and faculty from that country and the US who will share their expertise in an open exchange of ideas on a cross-cultural scale. Discussions will focus on prevention strategies, treatment modalities, and education methods designed to reach children, adults, and minorities. The AIDS crisis and high-risk addiction-related behavior also will be examined.

The program includes weekend homestay with Swedish families. For more information, contact: Dr. Alan M. Warne, Vice President for Programs, People to People International, 501 East Armour Blvd., Kansas City, MO 64109; tel: 816/531-4701.

Effect of a Gatekeeper Plan on Health Services Use and Charges: A Randomized Trial

DIANE P. MARTIN, PHD, PAULA DIEHR, PHD, KURT F. PRICE, MS, AND WILLIAM C. RICHARDSON, PHD

Abstract: A randomized trial was conducted to determine the effectiveness of a health care plan which uses physicians as gatekeepers to control health services use and charges. New enrollees in United Healthcare (UHC), an independent practice association, were randomly assigned to the standard UHC plan requiring a gatekeeper, or to an alternate plan with equal benefits but without a gatekeeper. Individuals in both plans were similar in demographic characteristics, perceived health status, and other health insurance coverage. The gatekeeper plan had 6 percent lower total charges per enrollee than the plan without a gatekeeper. There were minor differences in hospital use and charges. Ambulatory charges were $21 lower per person per year in the plan with a gatekeeper (95% CI = −39.9, −2.1) and these were due to .3 fewer visits to specialists (95% CI = −0.50, −0.10). We conclude that a health plan which incorporates incentives and penalties for physicians to act as gatekeepers can reduce the cost of ambulatory services by limiting specialist visits. (*Am J Public Health* 1989; 79:1628–1632.)

Introduction

Many health plans use a variety of mechanisms to encourage primary care physicians to act as "gatekeepers" in managing the medical care of their patients.[1,2] Incentives and penalties presumably will control cost by changing the gatekeeper's own practices and by limiting inappropriate hospital and referral care. The effectiveness of gatekeeper plans depends on the ability of participating physicians to coordinate the medical care system efficiently.

Gatekeepers are used by many health maintenance organizations (HMOs), independent practice associations, preferred provider organizations, and some Medicaid plans,[3,4] but evidence that they save money is lacking.[5] Descriptive data exist showing that gatekeepers can decrease the use of services if the physicians share financial risk of providing care,[6–8] but there are no data from controlled studies.

We therefore conducted a randomized trial of a plan using primary care physicians as gatekeepers to control health services use and charges. We randomly assigned study participants to United Healthcare, an independent practice association using gatekeepers, or to Northwest Healthcare, a plan with the same benefits but no gatekeeper. Because the economic incentives in the gatekeeper plan encouraged use of the gatekeeper and discouraged hospital and referral care, we expected that United Healthcare would have fewer hospitalizations, fewer visits to specialists, and lower use of procedures.

Methods

Population and Random Assignment

United Healthcare (UHC) was one of three health care plans available to Washington State employees in the Seattle metropolitan area during the 1979 open enrollment. All subscribers (n = 1,239) and their family members who enrolled in UHC for the first time were asked to participate in the experiment and complete an initial telephone interview. Retirees were excluded from the study.

The 90 percent of subscribers (families) who agreed to participate were assigned to a health plan according to a randomization scheme stratified by previous health care plan and type of employer, because State health insurance information showed that use of services differed significantly for these subgroups.[9] Previous health care plans were: Blue Cross of Washington and Alaska, which provided comprehensive inpatient and outpatient coverage; Group Health Cooperative of Puget Sound, a staff model HMO; or no previous State health plan, for new employees. The two types of employer were: an institution of higher education, or other State agency. We assigned 555 subscribers and their dependents (1,419 enrollees) to the standard United Healthcare plan with a gatekeeper and 558 subscribers (1,408 enrollees) to the plan without a gatekeeper, Northwest Healthcare.

The Two Plans

Both plans were offered by the SAFECO Insurance Company and had the same insurance premiums and benefits. Premiums for the subscriber and all dependents were paid in full by the State. Both plans provided inpatient, outpatient, and preventive care coverage with copayments and limits on maternity and mental health services. There was no deductible or coinsurance, but there were copayments of $2 for each prescription and $25 for each general physical examination.

The plan with a gatekeeper, United Healthcare, attempted to contain costs by enlisting primary care physicians in private practice as gatekeepers. The details of this plan have been published earlier.[10] When the present study began, most gatekeepers had been in the plan for two years. Hospitalization and other major procedures entailed no utilization review, prior authorization, or mandated second opinions, and there was little emphasis on quality assurance or provider education. Because gatekeepers had only 25 plan patients on average, capitation reimbursement was not practical, and almost all were reimbursed at 95 percent of their charges. Thus, primary care physicians had no financial incentive to limit costs of the care they provided.

There were stronger incentives for gatekeepers to monitor referral care. In 1979, referral care consumed 74 percent of the amount paid for health services by United Healthcare.[9] A risk-sharing account was established for each gatekeeper based on the age and sex of his or her panel of enrollees. These funds were then used to cover hospitalization, drugs, specialty, ancillary, and other referral costs. Catastrophic

costs greater than $5,000 per patient were paid by a reinsurance program. At the end of the year, the gatekeeper shared with United Healthcare any deficit or surplus remaining in the account. If there was a surplus in the account at the end of the year, it was split equally between the gatekeeper and UHC. If there was a deficit, the gatekeeper had to pay back what was over-spent, up to an amount equal to 10 percent of his fee-for-service charges. The financial risk was not great to the physician. If the account was overdrawn, the minimum reimbursement rate was 85 percent (95 percent initial payment minus 10 percent), which was considered to be a reasonable return on charges. Furthermore, the risk applied to only a small proportion of the physician's total practice.

UHC gatekeepers could refer patients to the specialists or hospitals of their choice. Referrals could be made only to a few types of non-physician health professionals such as optometrists, psychologists, chiropractors, and occupational and physical therapists. There were no financial incentives for specialists, non-physicians, or hospitals to practice efficient care, because they were paid 100 percent of their fee-for-service charges.

United Healthcare required each enrollee to select a primary care physician from a list (N = 391) of family physicians (46 percent), internists (22 percent), pediatricians (19 percent), obstetrician/gynecologists (11 percent), and the few general surgeons (2 percent) who had joined the plan as gatekeepers. The gatekeeper was responsible for providing primary care and coordinating referrals for specialty care, ancillary services, and hospitalization. If the enrollee received care from a specialist or visited an emergency room for non-urgent care without approval from the gatekeeper, UHC would not pay the claim and the enrollee was responsible for payment.

Enrollees in the plan without a gatekeeper, Northwest Healthcare, were not required to choose a gatekeeper or to obtain approval for hospitalization, emergency, or specialist visits. These enrollees could receive care from any physician or non-physician health care provider in the Seattle area and the plan would reimburse the provider 100 percent of charges. Many of the same physicians who joined United Healthcare as risk-sharing gatekeepers also saw patients in Northwest Healthcare and were reimbursed in full for charges by that plan. Whereas physicians' offices submitted all claims to United Healthcare, Northwest Healthcare enrollees were required to submit claims to the plan for payment. Northwest Healthcare enrollees were provided with addressed, stamped envelopes to facilitate claims submission.

Data Collection

The adult who made most of the health care decisions for the family was asked to complete a baseline telephone interview. Information obtained from the interview included family composition, demographic information, perceived health status, health insurance coverage, and usual source of health care. This information was used to stratify the random assignment to plans and assess the similarity of the two groups. Enrollees in both plans were followed for 12 months. Data on the use of health services and charges were collected from SAFECO computerized membership and claims records. At the end of the study, a questionnaire was mailed to participants to assess experience with the plans and other health insurance during the previous year and to ascertain out-of-pocket expenditures and satisfaction with the plans. The response rate for the mail questionnaire was 95 percent for each plan.

Charges and Use of Services

We examined charges, percentage of enrollees using any services, and volume of services overall and separated according to primary care physicians versus specialists; ambulatory versus hospital care; type of procedure; and diagnostic category. We partitioned the enrollees into nonusers and users of services as described by Duan, *et al*,[11] to separate differences in access to care from the effect of gatekeeper control once someone had entered the system.

Total billed charges for 12 months were calculated for each enrollee, including all charges by primary care providers, specialists, hospitals, and ancillary services. Billed charges, rather than the amount paid by SAFECO, were used to ensure comparability between plans. Payments for coordination of benefits were not taken into account.

We measured the percentage of enrollees using any services or a specific service during the study. We also measured the volume of services used per enrollee or per user, e.g., number of ambulatory care visits, hospital admissions and days.

Definition of Primary Care Physician

A physician was designated as a primary care physician (PCP) if he or she was a general or family practitioner, osteopath, pediatrician, general internist, or obstetrician/gynecologist. All other physicians were defined as specialists. Although we tested two other PCP definitions with similar results, we used this definition to make primary care physicians as similar as possible in the two plans. This was the most conservative definition because it tended to overestimate primary care physicians in the plan without a gatekeeper and therefore any differences in primary care physician use between the two plans would be underestimated.

Characteristics of Enrollees

Data obtained during the baseline telephone interview showed enrollees in the two plans to be similar in demographic characteristics, social structural variables, other insurance coverage, perceived health status, and usual source of health care (Table 1). Enrollees in the gatekeeper plan were more likely to have had internists, obstetrician/gynecologists, or other specialists as their usual source of care. Assuming that care by internists and specialists is more costly than care by family physicians,[12] this difference between groups might reduce the difference in cost between the two plans. On the other hand, internists or obstetrician/gynecologists might be able to handle problems that a family physician would refer to a specialist.

Analysis

The differences in the means or proportions of outcome measures and the 95% confidence intervals around those differences were calculated. Analysis of covariance was used to adjust for the control variables. In general, the plan differences remained significant after controlling for main and independent variables for all enrollees and for users.[9] Although there were few differences between the plans on key independent variables, many independent variables were significantly related to charges in both plans. Including these independent variables in the analysis did not change the findings of the univariate analysis in any substantial way, confirming the success of the randomized design. Because the adjusted and unadjusted results were essentially the same, the unadjusted rates are presented in this paper.*

*Data available on request to author.

TABLE 1—Selected Characteristics of Enrollees in Gatekeeper or No Gatekeeper Plans*

Characteristics	Gatekeeper (n = 1419)	No Gatekeeper (n = 1408)
Age (years)		
0–5	9.2%	8.3%
6–17	24.3	24.6
18–44	52.6	50.7
45+	13.7	16.4
	26.9	27.7
Mean (years)

Subscriber Years of Education		
Mean years	15.6	15.7
S.D.	3.2	3.1
Spouse Years of Education		
Mean years	15.1	14.8
S.D.	2.9	2.9
Family Income		
Under $10,000	15.1%	16.2%
$10,000–20,000	43.1	41.4
$20,000–30,000	25.8	26.1
Over $30,000	16.0	16.4
Other Health Insurance Coverage	27.9%	27.5%
Perceived Health Status		
Excellent	73.6%	74.0%
Good	23.0	23.4
Fair	3.3	2.2
Poor	.1	.4
Had a Usual Source of Care before Study Period	82.9%	84.2%
Usual Source of Care Was a UHC gatekeeper	45.4%	49.5%
Specialty of Usual Source of Care before Study Period		
Family/General Practitioner	49.6%	57.1%
Pediatrician	22.7	21.7
Internist	13.9	9.5
Obstetrician/Gynecologist	8.0	6.2
Other	5.8	5.5
Months Membership in Plan During Study		
Mean months	10.5	10.3
S.D.	2.2	2.3

*Other characteristics which were measured but are not presented here due to small differences between plans include: marital status, family composition, family health risk scale, employment status, months residence in community, and type of health insurance coverage.

Results

Use and Charges for All Enrollees

Access to care, as reflected by the percentage of enrollees using any services or having at least one ambulatory visit, was high in both plans (Table 2). People in the gatekeeper plan had more visits to a primary care physician (difference = 6%, 95% CI = 2.43, 9.57) and fewer visits to a specialist (difference = −9%, 95% CI = −12.28, −5.72). Ambulatory charges per enrollee were $21 lower in the gatekeeper plan (95% CI = −39.9, −2.1, Table 3), due to significantly fewer visits to specialists.

There were minor differences between plans in hospital use and charges per enrollee (Tables 2 and 3). The gatekeeper plan had lower hospital use than the no gatekeeper plan (Table 4). The plans had similar inpatient charges for specific services, such as medical, surgical, laboratory, and radiological procedures (data not shown).*

Charges and Visits for Ambulatory Care

We examined the effect of the gatekeeper plan among those people who used ambulatory services. PCP ambulatory visits and charges for users were similar, but users in the gatekeeper plan had significantly fewer visits to specialists and lower specialist charges (Table 5).

There were no differences between plans in primary care physicians' use of surgical, laboratory, or radiological procedures, as defined by categories of Current Procedural Terminology codes (data not shown). PCPs in the gatekeeper plan ordered or performed fewer medical procedures on their patients than did PCPs in the no gatekeeper plan (difference = −4%, 95% CI = −5.13, −2.87). Specialists in both plans had similar use and charges for various types of procedures.

We also compared ambulatory use between plans for 20 common diagnostic categories and found that people in the gatekeeper plan had fewer visits for mental health problems, back problems, and acute and chronic respiratory problems, and more of their visits for these problems were with a PCP rather than a specialist (data not presented).*

Experience Using the Plans

The end-of-study survey showed no difference between plans in enrollees' use of other health insurance plans, in the proportion of claims submitted, or in out-of-pocket expenditures during the study period. Enrollees in the gatekeeper plan more often identified internists, obstetrician/gynecologists, and specialists as their usual providers of care, while enrollees in the no gatekeeper plan had more often named family physicians (the distribution is similar to source of care before the study, Table 1). Enrollees were more satisfied with the no gatekeeper plan than the gatekeeper plan (very satisfied: 75% − 64% = 11%, 95% CI = 7.63, 14.37).

TABLE 2—Percentage of Enrollees Using Services in the Gatekeeper and No Gatekeeper Plans

Percentage of Enrollees With:	Gatekeeper (n = 1419)	No Gatekeeper (n = 1408)	Difference (95% CI)
	%	%	
Any Services	74	77	−3 (−6.17, +0.17)
≥1 Ambulatory Visit	68	70	−2 (−5.41, +1.41)
≥1 Primary Care Physician Visit	65	59	+6 (+2.43, +9.57)
≥1 Specialist Visit	23	32	−9 (−12.28, −5.72)
≥1 Hospitalization	4.5	5.0	−0.5 (−2.07, +1.07)

TABLE 3—Annual Charges and Visits for Enrollees in the Gatekeeper and No Gatekeeper Plans

	Gatekeeper (n = 1419) Mean	No Gatekeeper (n = 1408) Mean	Difference (95% CI)
Total Charges	$239	$254	−15 (−73.0, +43.0)
Primary Care Physician	85	96	−11 (−24.4, +2.4)
Specialist	155	158	−3 (−52.8, +46.8)
Hospital Charges	$ 93	$ 87	+6 (−44.9, +56.9)
Primary Care Physician	9	16	−7 (−15.4, +1.4)
Specialist	84	71	+13 (−32.2, +58.2)
Ambulatory Charges	$146	$167	−21 (−39.9, −2.1)
Primary Care Physician	76	80	−4 (−13.2, +5.2)
Specialist	70	87	−17 (−30.1, −3.9)

TABLE 4—Hospital Use for Enrollees in the Gatekeeper and No Gatekeeper Plans*

	Gatekeeper Mean	No Gatekeeper Mean	Difference (95% CI)
Hospital Admissions per 1000 Person Years	49	56	−7 (−25.1, +11.1)
Hospital Days per 1000 Person Years	205	277	−72 (−207.8, +63.8)
Average Length of Hospital Stay	4.2	4.9	−0.7 (−2.7, +1.3)
Hospital Charges			
Primary Care Physician	$ 196	$ 320	−124 (−280.4, +32.4)
Specialist	$1867	$1432	+435 (−378.9, +1248.9)

*The gatekeeper plan had 64 persons with a total of 70 hospitalizations, and the no gatekeeper plan had 70 persons with a total of 79 hospitalizations.

TABLE 5—Charges and Visits for Ambulatory Users in the Gatekeeper and No Gatekeeper Plans

Per User Per Year	Gatekeeper (n = 1052) Mean	No Gatekeeper (n = 1087) Mean	Difference (95% CI)
Ambulatory Charges	$197	$216	−19 (−42.4, +4.4)
Primary Care Physician	102	104	−2 (−13.3, +9.3)
Specialist	95	113	−18 (−34.8, −1.2)
Ambulatory Visits	4.0	4.3	−0.3 (−0.72, +0.12)
Primary Care Physician	3.1	2.9	+0.2 (−0.08, +0.48)
Specialist	.9	1.3	−0.4 (−0.67, −0.09)

Although satisfaction differed, similar percentages of families switched to other plans during the next open enrollment.

Discussion

In this randomized trial, the gatekeeper plan had lower ambulatory charges per enrollee, primarily due to lower use of specialists. The gatekeeper plan had little impact on hospital use or charges perhaps because of small numbers. The total charges per enrollee were 6 percent lower in the plan with a gatekeeper, a modest difference that was not statistically significant.

The gatekeeper plan required patients to see a primary care physician first, so it was not surprising to find that more enrollees in the gatekeeper plan had a visit to a primary care physician. The gatekeeper plan provided no incentives for PCPs to reduce visits to themselves, and indeed PCP visits and charges were similar in the two plans. There were incentives for gatekeepers to limit referrals and this apparently resulted in lower expenditures for specialist services in the gatekeeper plan. Specialists were offered no incentives by the gatekeeper plan to reduce costs, and once patients were referred to specialists, their volume and charges for various types of procedures were similar in both plans.

A gatekeeper effect was seen for certain diagnoses for which treatment is at the discretion of the patient and physician, such as mental health problems and back problems. We do not know if these differences result from: self-selection, decreased initial visits by the enrollee, differences in diagnostic coding, or the practice patterns or specialty of the regular doctor. Future studies of gatekeeper plans should explore utilization by diagnostic category in more detail.

True gatekeeper effects are probably at least as large as those reported here. First, the population consisted of subscribers and their family members who chose United Healthcare rather than one of the other state health insurance options available to them. Because the pre-enrollment information described the standard UHC plan, all study participants may

have been oriented to use PCPs more than the general population; therefore, the differences between the plans may be underestimated. Second, differences between plans may have been underestimated because people in the no gatekeeper plan were more likely to have a regular doctor who was already participating in United Healthcare as a gatekeeper.

Two other issues should be considered when interpreting these results. First, we could not examine the gatekeeper plan effect in more detail because we were using claims data. We have no indication whether a specific visit was initiated by the patient or provider, or whether the patient was seeing a particular provider as a primary care physician or as a specialist. Furthermore, claims data did not allow us to describe how or to what extent a primary care physician was functioning as a gatekeeper. Second, this 12-month study period may not be representative of the plans' or enrollees' experience over time. One possibility is that individuals in the no gatekeeper plan may have used services differently because they knew that the study period was limited to one year. Another possibility is that the "learning period" for new enrollees may have affected the results. We would expect this learning period to be more important for the gatekeeper plan because enrollees had to adjust to more restrictions on their use of services than in the no gatekeeper plan.

Other studies have reported mixed results of the gatekeeper effect on the use of services. Catlin, *et al*, surveyed use of primary care physicians in staff and group model HMOs and excluded independent practice associations (IPAs).[6] They found no significant differences in hospital or ambulatory use among HMOs using more primary care physicians, but the financial incentives offered to primary care physicians were not described. Burkett's descriptive study of an IPA-HMO with gatekeepers and financial incentives similar to UHC found the rate of referral visits to be low.[8] In comparing his results to ours, primary care visits per person per year appeared to be slightly higher and use of referral visits even lower than those in this study.

The findings of another study of UHC conducted at about the same time provide additional evidence for assessing the gatekeeper concept. In that study, we compared the standard UHC gatekeeper plan with two other health plans: Group Health Cooperative, a staff model HMO with primary care case management; and Blue Cross, which provided fee-for-service hospital and ambulatory care. Use and estimated expenditures were compared across the three plans for a different cohort of Washington State employees which was followed for two years.[9] Initial access to care was high at both UHC and Group Health. UHC had lower expenditures for specialists than the other plans, but the savings were not sufficient to decrease overall expenditures. Total annual expenditures per person were similar for UHC and Blue Cross and were significantly higher than expenditures for Group Health.

These two studies of United Healthcare, using different study designs, both reported savings on specialist costs in the UHC gatekeeper plan compared to other plans. However, incentives for gatekeepers alone may not be sufficient to contain overall plan costs. In a subsequent case study of United Healthcare, we examined charges for all enrollees from numerous employers in three states. Although United Healthcare may have contained specialist charges, from 1979 to 1982 specialist charges as a percentage of total charges rose, whereas the percentage of charges by gatekeepers fell.[13]

After operating for nine years in Washington, California, and Utah, United Healthcare was discontinued by SAFECO because of large financial losses, due to management problems and inadequate incentives for specialists and consumers to control costs.[14] The evidence presented in this study suggests that the gatekeeper concept actually may have reduced UHC losses.

Hillman describes the conflict of interest that may exist between financial incentives and providing high quality care.[2] Whenever utilization decreases, especially for referral care, the question of underutilization of services arises. There is no evidence from our studies or those of others which shows plans with gatekeepers providing higher or lower quality care than other plans. Our study was too small to observe any differences in the overall quality of care.

The results of this study are particularly relevant to independent practice associations with incentives similar to United Healthcare. (Since our study population represents employees and their families, these results may not apply to the poor or to retirees.) As the number of gatekeeper plans in the United States continues to grow, the findings of this study have important implications for the design of those plans. First, the United Healthcare incentives for channeling enrollees to primary care physicians increased enrollees' initial use of PCPs and decreased the use of specialists. Second, relatively small financial incentives were sufficient to decrease primary care physician referrals to specialists. It should be emphasized that these incentives applied only to a small proportion of a primarily fee-for-service based practice. Third, the finding of no difference between plans in specialists' use of procedures suggests that in the future plans should incorporate incentives for cost control by specialists.

Increased Suppressor T Cells in Probable Transmitters of Human Immunodeficiency Virus Infection

GEORGE R. SEAGE III, MPH, C. ROBERT HORSBURGH, JR, MD, ANN M. HARDY, DRPH, KENNETH H. MAYER, MD, M. ANITA BARRY, MD, MPH, JEROME E. GROOPMAN, MD, HAROLD W. JAFFE, MD, AND GEORGE A. LAMB, MD

Abstract: To evaluate behavioral and immunologic factors related to transmission of human immunodeficiency virus (HIV) by homosexual intercourse, we studied a population of 329 homosexual/bisexual men (155 partner-pairs) seen in a community health center and medical outpatient clinic. Logistic regression analysis showed that behavioral risk factors for infection in the 130 HIV-infected men included: receptive anal intercourse (OR 4.6, 95% CI-1.8, 12.1); receptive fisting (OR 2.5, CI-1.1, 7.0); nitrite use (OR 2.3, CI-1.2, 4.6); history of gonorrhea or syphilis (OR 2.3, CI-1.4, 3.9); and history of sexual contact with men from areas with many AIDS cases (OR 1.9, CI-1.0, 3.5). Comparing seven men who were probable transmitters of HIV and 11 men who had not transmitted HIV to their uninfected partners despite unprotected insertive anal intercourse, we found no differences in HIV isolation from peripheral blood mononuclear cells, circulating HIV antigen detection, or presence of neutralizing antibody to HIV. Helper T-cell numbers were not significantly different between the two groups, but transmitters had more suppressor T-cells than did nontransmitters. (*Am J Public Health* 1989; 79:1638–1642.)

Introduction

The major behavioral risk factors in the transmission of human immunodeficiency virus (HIV) in homosexual/bisexual men include receptive anogenital sexual contact and a large number of sex partners.[1–3] However, some men with many receptive anal sexual contacts remain uninfected while others with infrequent contact become infected.[4,5] Thus, while particular sexual behaviors may increase the likelihood of HIV transmission, other factors presumably contribute to the efficiency of sexual transmission of the virus.

Transmission of HIV requires that the infected partner transmit the virus and that the exposed partner be susceptible to the infection. Studies of susceptibility to HIV infection of exposed persons have failed to reveal either immunologic or genetic susceptibility factors.[6,7] However, several studies have shown a correlation between worsening clinical status or declining numbers of helper T cells in the HIV-infected partner and increased transmission of HIV.[8–12]

In this study, we evaluated the role of specific sex practices in HIV transmission among homosexual men. We also examined the relation of immunologic laboratory parameters to transmission by comparing seropositive men who appeared to have infected their partners with seropositive men who did not infect their partners despite unprotected insertive anal intercourse.

Methods

Selection of Study Participants

Men were eligible for enrollment in our study if they were homosexual or bisexual, were 18 years of age or older, and resided within the Boston, Massachusetts Standard Metropolitan Statistical Area. Men were seen at the Fenway Community Health Center (FCHC) and/or the New England Deaconess Hospital. AIDS was diagnosed according to the Centers for Disease Control (CDC) classification system (Group IV subgroups C-1 and D-2); AIDS-related complex (ARC) was defined as CDC classification group III (persistent generalized lymphadenopathy), IV-A (fever, weight loss or diarrhea), or C-2.[13] Asymptomatic men were those without AIDS or ARC. Sexual contact was defined as orogenital, anogenital, or oroanal contact involving an exchange of body fluids and/or penetration.

We recruited asymptomatic participants from: men who had at least one visit to the FCHC from May 1984 through March 1987; men referred by friends or physicians outside of the FCHC; advertisements soliciting participation in the study placed in two newspapers; and men referred by persons already enrolled in the study. The protocol for this study was approved by the Human Studies Committees of all participating institutions.

Data Collection

At enrollment, all participants were interviewed to obtain data on demographic characteristics, occupational and travel histories, sexual behaviors, and drug and alcohol use. A complete medical history was obtained for the five years before study enrollment, and a standard clinical examination was performed. All participants were counseled regarding high- and low-risk sex practices and ways to reduce their risk for HIV infection.

Laboratory Studies

All participants were evaluated with a complete blood count (CBC) and lymphocyte subset determination, performed using specific monoclonal antibodies (Ortho Diagnostics, Raritan, NJ). Antibodies to HIV were determined by an enzyme immunoassay (EIA) (Abbott Laboratories, Chicago, IL). All serum samples initially positive by EIA and selected other serum samples (as specified later) were examined by Western blot using previously described methods.[14] Culture of HIV was performed in H9 cells, and reverse transcriptase activity was measured by standard techniques.[15] Antigen-capture assay for HIV employed a sandwich EIA using polystyrene beads coated with human anti-HIV (Abbott Laboratories, Chicago, IL).[16] Neutralizing antibody assays were performed in H9 cells with the HTLV-IIIB isolate of HIV using a modification of the method of

Robert-Guroff.[17] The assay was performed by mixing 100 50 percent tissue culture infectious doses of HIV with 200 ml of heat-inactivated human serum at various dilutions, and incubating at 4°C for 1.5 hours. Virus was then absorbed onto 1×10^6 H9 cells for one hour and incubated at 37°C. Neutralization titer was defined as positive when the assay blocked 90 percent or more of the control virus infection at a 1:20 dilution.

Statistical Analysis

Confidence intervals for infection rates were calculated based on the chi-square function method of Miettinen.[18] Exposure variables were categorized depending on the distribution of the variable without regard to serologic status. Unadjusted prevalence odds (exposure odds) ratios were estimated and exact 95% confidence intervals (CI) calculated by the method of Rothman.[19] Adjusted estimates were maximum likelihood estimates from logistic regression and 95% CI were calculated using the standard errors of the beta estimates.[20] Continuous laboratory variables were compared using the Wilcoxon 2-sample test.[20] Dichotomous laboratory variables were compared by Fisher's exact test.[20]

Results

All interview information and laboratory samples were obtained at the initial enrollment visit. Three hundred twenty-nine men were enrolled in the study: 23 men had AIDS, 31 had ARC, and 275 were asymptomatic. Six participants were linked to three partners, 12 to two partners, 113 to one partner, and 43 to no partner, for a total of 155 partner-pairs.

The mean age of the study participants was 32.8 years; mean level of education 16 years; median income $10,000–$19,999; and mean length of time residing in metropolitan Boston 144 months. Ten percent of the men had been married; 316 (96%) were White, 9 (3%) were Black, and four (1%) were Hispanic.

One hundred thirty (40%) men were HIV-seropositive, while 199 (60%) were seronegative. Of the 155 partner-pairs, 62 (40%) were concordant seronegatives, 35 (23%) were concordant seropositives, and 58 (37%) were discordant (one seropositive and one seronegative partner). Thirteen of 24 partners (54%) of men with AIDS were seropositive (95% CI 34, 74); 12 of 31 partners (39%) of men with ARC were seropositive (CI 22, 57); 10 of 24 partners (42%) of asymptomatic seropositive men were seropositive (CI 23, 61).

Sexual Practices

To determine which potential risk factors were associated with seropositivity, we analyzed all 329 men in the cohort. In bivariate analysis, six variables were associated with antibody to HIV: number of sex partners in the previous five years; receptive anal sexual activity; receptive oral sexual activity; receptive fisting; sexual contact with persons from areas of high HIV prevalence; history of gonorrhea or syphilis; use of nitrites; and use of other illicit drugs (Table 1).

TABLE 1—Distribution (%), Crude and Adjusted Relative Odds for HIV Infection by Behavioral Risk Factors

a) Adjusted using a logistic regression model that included age and the variables listed in this table.
b) New York City, San Francisco, Los Angeles, and/or Miami.
c) Marijuana, cocaine, PCP, LSD, and/or quaaludes.

A logistic regression model was developed to assess potential confounding by any of the variables significantly associated with HIV antibody in the bivariate analysis. Factors that correlated with seropositivity in the multiple regression model were: receptive anal sexual activity; receptive fisting; nitrite use; history of gonorrhea or syphilis; and sexual contact with persons from areas of high HIV prevalence (Table 1).

Characteristics of Transmitters

We examined partner-pairs in which both partners were seropositive to identify possible transmitters. Ten partner-pairs were identified in which one partner had had over 80 percent of his receptive anal contacts within the relationship (in no case did both partners have over 80 percent of their receptive anal contacts with each other). The partner whose contacts were in large part within the relationship was therefore presumed to have been infected by the other (more sexually active) partner, who was designated the likely transmitter. Peripheral blood cells were available from seven of the transmitters; of these, four had a partner who had no receptive anal intercourse with any other partner, while the other three had partners with 4, 13, and 14 episodes outside the relationship.

Partner-pairs in which one partner was seropositive and one was seronegative were examined to identify men who had exposed their partner to HIV without transmitting infection. All seronegative men were confirmed to be uninfected by negative Western blot and HIV antigen assay. Since we could not be certain that the seropositive partner was positive more than a short time before entry into the study, we excluded partner-pairs who had not had at least six episodes in which the seronegative partner had receptive anal intercourse with an insertive seropositive partner during the six-months before entry into the study. The HIV seropositive partners in these partner-pairs were designated the likely nontransmitters. Sixteen nontransmitters were identified. Peripheral blood cells were available from 11 of these men.

One of the transmitters had AIDS and three had ARC; no nontransmitters had AIDS but three had ARC. Transmitters had longer relationships with their partner (mean ± SD: 58 ± 24 months) than did nontransmitters (36 ± 36 months), but transmitters had fewer total episodes of insertive anal intercourse with their partner (151 ± 185 episodes) than nontransmitters (192 ± 192 episodes). Neither difference was statistically significant. No differences were noted between transmitters and nontransmitters in history of syphilis, gonorrhea, hepatitis B, herpes simplex, herpes zoster, or cytomegalovirus infection, or infectious mononucleosis. Furthermore, transmitters and nontransmitters had similar histories of fever, skin rash, and enlarged lymph nodes.

Transmitters did not differ from nontransmitters with respect to circulating HIV antigen, presence of neutralizing antibody to HIV, or ability to recover virus from peripheral blood mononuclear cells (Table 2). Phenotyping of peripheral blood mononuclear cells of transmitters revealed a median of 1150 total T cells, 430 helper T cells, 960 suppressor T cells, and a median helper/suppressor ratio of 0.40; nontransmitters had a median of 1170 total T cells, 390 helper T cells, 650 suppressor T cells, and a median helper/suppressor ratio of 0.80 (Figure 1). While total and helper T-cell numbers were similar in both groups, transmitters had higher suppressor T-cell numbers than did nontransmitters (Wilcoxon, $p = < .02$). Helper/suppressor ratios were lower in transmitters than in nontransmitters (Wilcoxon, $p = .12$). Five of the six transmitters with elevated suppressor cells were re-evaluated after 12 months; only one had persistently elevated suppressor cells.

TABLE 2—Distribution (%) of Laboratory Parameters in Transmitters and Nontransmitters

Parameter	Transmitters (%)	Nontransmitters (%)
HIV culture	1/5 (20)	3/9 (33)
Circulating HIV antigen	1/7 (20)	4/13 (31)
Neutralizing antibody to HIV	3/3 (100)	3/7 (43)

Discussion

Several studies have shown that the major risk factors for acquisition of infection among homosexual men are exposure to a large number of sex partners and exposure to infected persons by receptive anal intercourse.[1–3] Demographic and behavioral analysis of our cohort affirms that it is similar to previously reported cohorts. We assessed risk by estimating exposure odds ratios for HIV infection. The interpretation of such ratios can be difficult when both the temporal sequence and the duration of exposure are unknown. In some cases, the relevant period of risk may have been overestimated, resulting in exposure odds ratios that underestimate the true values.

The risk of acquiring HIV infection was positively correlated with increased number of sex partners with whom the person was the receptive anal sex partner. In our analysis, both fisting and use of nitrites were also associated with seropositivity after controlling for confounding. Fisting might facilitate HIV transmission by causing rectal trauma, thereby allowing virus to bypass mucosal defenses. The biologic mechanism for the increased risk in nitrite users is unclear; the role of nitrites as potential effect modifiers needs to be assessed further.

While these practices are associated with an increased risk of becoming infected with HIV, they do not assure it. Many persons appear to be sexually exposed to HIV on multiple occasions, yet do not become infected.[4,5] Possible explanations for this phenomenon are that some persons are more efficient transmitters than others; that some persons, when exposed, are more susceptible than others; or both.

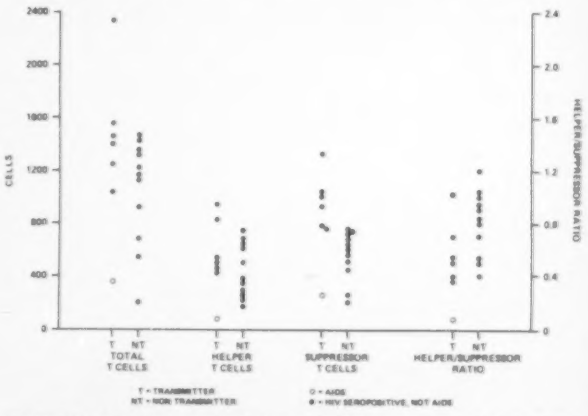

FIGURE 1—T-cell Phenotypic Markers in HIV Transmitters and Nontransmitters; Transmitters had Higher Numbers of Suppressor T-cells

Since previous studies have failed to identify genetic or immunologic susceptibility factors for HIV infection,[6,7] we focused our investigation on factors relating to transmission.

Partner-pairs in which both partners were seropositive were analyzed to select a group of men who were most likely to have transmitted infection to their partners. Such a determination would ideally require that a seropositive man have only been exposed to a single seropositive partner during the time the virus could be assumed to have been circulating in the community. However, monogamous relationships were rare in our cohort. We therefore computed a scale of relative fidelity for each partner. Seven partner-pairs included a man who had had more than 80 percent of his receptive anal contacts since the end of 1981 with one seropositive person (four had 100 percent of their contacts with the presumed transmitter). Therefore, although the date of HIV transmission could not be definitively established and contact with other seropositive partners could not always be completely excluded, we feel the anal insertive partners in these relationships were likely HIV transmitters.

Because of the retrospective nature of the study, the dates of infection of the possible transmitters and nontransmitters were unknown and the exact duration of exposure could not be established. However, the duration of relationships was not significantly different between transmitters and nontransmitters. Moreover, similar numbers of potentially infective episodes were reported for both transmitters and nontransmitters.

We found increased suppressor cells in HIV transmitters. This suggests a role for host immunity in modulating infectiousness by controlling the amount of virus present in host secretions and thereby regulating the dose of virus to which a sex partner is exposed. We were not able to measure the amount of virus in the semen of our transmitters and nontransmitters. However, no relationship was seen between the ability to culture virus from the blood, the presence of neutralizing antibody, or the presence of p24 antigen and the ability to transmit HIV. This may have been due to the small number of samples available for study; alternatively, the presence of detectable HIV in blood may not be related to the presence of infectious virus in semen.

Increased suppressor T-cell numbers have been reported in primary HIV infection.[21] The transmitters in our study therefore may have recently experienced acute HIV infection. Alternatively, since many infectious processes (notably herpes virus infections) can temporarily increase suppressor cells,[22,23] increased suppressor cells in our transmitters may be a marker of an intercurrent infectious process other than HIV infection. Such a process might increase HIV replication by activating HIV amplification genes[24,25] or by interfering with the as yet unknown mechanisms that permit the host to at least temporarily control HIV replication.

Our results suggest that some men with higher numbers of suppressor cells may be more infectious to their sex partners than other infected men. Francis, *et al,* have also reported increased suppressor cells in mothers who appeared to have transmitted HIV to their neonates.[26] On the other hand, several studies have found that HIV-infected men with low helper T-cell numbers or advanced HIV infection are more likely to transmit HIV to their female partners.[8–12] Our HIV-infected subjects were largely asymptomatic with relatively normal numbers of helper T cells; thus we would not have expected to detect transmission by many men with AIDS or low numbers of T-helper cells. Our observations thus support the hypothesis that HIV infectivity is not limited to the period of immunodeficiency seen with advanced HIV infection.[27]

ACKNOWLEDGMENTS

The authors thank Scott Holmberg, MD, for assistance with this study and review of the manuscript. We thank Martha Moon, RNP, P. Clay Stephens, PA, Robert McCarthy, RNP, J. Davis Allen, MD, Helen Fitch, RN, and Joan Pellitier, RN for their clinical help. Patrick Riggs, Daniel Reed, Janet Bath, and Julie Marston interviewed the study participants, while Lindsey Schneider, Paige M. Bracci, and Tim Bush performed data entry, management, and programming and assisted with the data analysis. W. Mead Morgan consulted with us regarding data analysis. We especially want to thank the staffs of the Fenway Community Health Center and the New England Deaconess Hospital for their invaluable assistance in the performance of this study. Most of all, we are indebted to the participants in the study for their time, effort, and trust in us to perform this difficult and demanding research.

1987 National Medical Expenditure Survey Data Available on Magnetic Tape

The 1987 National Medical Expenditure Survey (NMES), a nationwide survey sponsored by the National Center for Health Services Research, is available from the National Technical Information Service (NTIS) on magnetic tape. The Institutional Population Component was designed to yield national estimates of the use of, and expenditures for, care during 1987 by persons who reside in nursing homes or facilities for the mentally retarded.

The files contain data from two Phase I instruments: the Facility Questionnaire and the Baseline Questionnaire.

- The Facility Questionnaire was collected from approximately 1400 participating facilities, and the data records contain bed size, type of ownership, facility certification, services routinely provided, average cost, and other information.
- The Baseline Questionnaire file contains data collected from approximately 6,900 persons who were residing in the sampled facilities, and include sociodemographic information such as age, race, sex, information on residences prior to admission, measures of functional limitations and chronic condition, and the work history of persons in facilities for the mentally retarded.

Documentation is provided with the tape and includes a description of NMES, questionnaires, and technical information on sample design, weights, and variance estimation. The NMES is available in EBCDIC or SAS format, and is contained on 9 track, half-inch tape only. Specify density requirement (1600 or 6250 bpi) when ordering.

PB89-178461KNC, *National Medical Expenditure Survey: Institutional Population Component, Phase I (EBCDIC Files)* 1987, $325 plus $3 handling fee.

A Survival Analysis of Hospitalization among Patients with Acquired Immunodeficiency Syndrome

CHARLES P. QUESENBERRY, JR., PHD, BRUCE FIREMAN, ROBERT A. HIATT, MD, PHD, AND JOSEPH V. SELBY, MD, MPH

Abstract: Survival analysis techniques were used in estimating lifetime inpatient utilization among patients diagnosed with acquired immunodeficiency syndrome (AIDS) using data on 863 members of the Kaiser Permanente Medical Care Program in the Northern California Region diagnosed with AIDS between January 1, 1981 and June 30, 1987. Using information on both deceased and living patients, we estimated means of 40.3 lifetime inpatient days and 3.3 hospitalizations among all AIDS patients. Those presenting with Kaposi's sarcoma experienced a mean of 7.6 fewer lifetime inpatient days than those presenting with *Pneumocystis carinii* pneumonia (95% confidence interval = .61, 14.6) and a mean of 11.0 (3.9, 18.6) fewer inpatient days than all other AIDS patients. Older patients had fewer hospital admissions than younger ones. Year of diagnosis does not appear to be related to lifetime utilization, and there is an indication that increased survival has been accompanied by decreased inpatient utilization intensity as measured on a per person-year basis. We recommend the use of survival analysis methods in the study of utilization among groups of patients with incomplete follow-up. (*Am J Public Health* 1989; 79:1643–1647.)

Introduction

The cost of providing health care for patients with acquired immunodeficiency syndrome (AIDS) continues to be of national concern. Recent research on the economic impact of the epidemic has provided different estimates of the mean lifetime cost per AIDS patient, ranging from $23,000 to $168,000.[1–6] Much of the variability can be attributed to differences in estimates of the mean lifetime inpatient days accrued by AIDS patients.[1] The disparity in these estimates of inpatient utilization is due in part to true differences across the populations from which the samples of patients were drawn but also in part to the different sampling and estimation techniques. Some investigators have restricted the sample to patients who have died during a given time period, which generally results in a sample biased toward shorter lived individuals. Using survival analysis techniques, we provide estimates of the distribution of lifetime hospitalizations and inpatient days in a large well-defined sample of both deceased and living patients with AIDS.

Methods

Data Collection

We identified 863 cases of AIDS diagnosed between January 1, 1981 and June 30, 1987 who were members of the Kaiser Permanente Medical Care Program in the Northern California Region (KPNCR), a private nonprofit prepaid group practice program with over two million members receiving care in 11 counties; these include the San Francisco Bay Area, a region which has experienced a relatively high incidence of AIDS. According to the California State Health Department, as of June 30, 1987, 4,251 cases were reported in the geographic area served by the Health Plan; we estimate that over 20 percent of these cases were members of the Kaiser Permanente Medical Care Program.

AIDS cases were identified retrospectively by obtaining reports from infection control nurses, and by examining three computerized datasets:

- the Inpatient Utilization System file which contains a record for each hospitalization at any Kaiser Foundation hospital including up to 13 diagnostic codes (*International Classification of Diseases, 9th Revision, Clinical Modification* (ICD-9)) per admission;
- pathology files containing biopsy reports from five major KPNCR hospital pathology departments; and
- a file maintained by the Health Plan's regional pharmacy administration containing all patients who had received zidovudine (AZT).

Each hospital admission from January 1, 1981 through June 30, 1987 was scanned for ICD-9 codes used specifically for AIDS: 279.10 and 279.19, which were used prior to October 1986, and 042.0, 042.1, 042.2, and 042.9 which were used subsequently. In addition, possible cases were identified by searching the hospitalization file diagnosis codes for AIDS-related conditions included in the Centers for Disease Control (CDC) case definition of AIDS.[7] Possible cases were also identified by searching the pathology files for diagnoses of Kaposi's sarcoma, *Pneumocystis carinii* pneumonia, candidiasis, and certain non-Hodgkin's lymphomas indicative of AIDS. For cases identified through the pathology file only or the AZT file only, the medical records were reviewed to verify the presence of AIDS. The medical records of those on the hospitalization file with a possible AIDS diagnosis were also reviewed. Patients were removed from the sample if the CDC criteria were not met.

Analyses are based on the 863 AIDS cases confirmed by chart review (N = 166), infection control nurse reports (N = 171), hospitalization records with diagnosis codes for AIDS (N = 506), and those on the AZT file with an additional record of an AIDS-related infection or neoplasm on the hospitalization or pathology files (N = 5). Males less than 60 years old with a biopsy report of Kaposi's sarcoma and no other source of confirmation were also included (N = 15).

For each case, date of diagnosis and diseases present on that date were obtained from the source of diagnosis confirmation. For those not confirmed either by chart review or nurse report, the earliest biopsy report or hospitalization record with an AIDS-related ICD-9 code was used. Sex and date of birth were obtained from computerized Health Plan

membership files. It is unlikely that there are patients in this case file who do not have AIDS, but it is possible that some Health Plan members diagnosed with AIDS are not included. Given the variety of sources used to identify AIDS patients, however, the number of unidentified cases is probably small.

The hospitalization file was used to obtain for each of the 863 cases the number of hospitalizations and total inpatient days from date of diagnosis to either date of death, date of leaving the Health Plan, or June 30, 1987, the end of this study. Date of death was obtained by a linkage to death records using the California Automated Mortality Linkage System.[8] Health Plan membership files were used to identify either date of leaving the plan or continued membership in the plan until death or June 30, 1987.

Data Analysis

While survival analysis techniques are often used to study time to an event such as death or onset of disease, these statistical methods are also appropriate for analyzing other random variables.[9,10] One of the main features of these methods is that the random variable of interest can be censored, which occurs when follow-up is incomplete. Information is provided by a censored observation because the final outcome will be at least as great as the measurement taken when follow-up is halted. In this study, a patient's lifetime number of hospitalizations and inpatient days were censored by leaving the Health Plan (N = 13) or by surviving through June 1987 and remaining in the plan (N = 348). We considered a patient's complete lifetime utilization to be measured only if death in the health plan occurred prior to June 30, 1987. The application of these statistical methods to the analysis of inpatient utilization is analogous to the analysis of survival time; we are treating inpatient utilization just as one would treat survival time or any other random variable subject to censoring.

The distributions of survival time, lifetime hospitalizations, and inpatient days were estimated by using the product-limit (Kaplan-Meier) method[11]; associated 95% confidence intervals were formed using Greenwood's estimation method.[12] This method provided estimates of the mean, median, and other percentiles of the distributions of inpatient utilization and survival time. Because lifetime hospitalizations as opposed to lifetime hospital days takes one of a very limited number of values, the sample median and other percentiles are less informative than the proportion of patients attaining selected values, and we present product-limit estimates of the latter. The log rank test[13] was used to assess differences in inpatient utilization distributions across subgroups defined by age, diagnosis at presentation and diagnosis date.

As an alternative to measuring hospital utilization from diagnosis to death of an AIDS patient, utilization rates on a per person-year basis and average length of stay estimates are also presented. Hospitalization and inpatient day rates are calculated for each time period as the observed number of events among AIDS patients divided by the total follow-up time for the cohort in that period. When study subjects enter and exit at any point during the year, this rate is a more appropriate measure of annual utilization intensity than statistics based on annualized data (e.g., multiplying by 12 the utilization by a patient observed for one month). Average length of stay is calculated as the mean number of inpatient days among all admissions during the given time period.

SAS was used for all data analyses[14]; the LIFETEST procedure was used to obtain product-limit estimates of distribution functions, means and percentiles, and to perform log rank tests.

Results

Patient characteristics are listed in Table 1. The mean age at diagnosis was 39.3 years; 98.7 percent were male. Fifty percent of the cases presented with *P. carinii* pneumonia only, and 16.1 percent presented with Kaposi's sarcoma only. Other opportunistic infections accounted for 17.7 percent of the cases. The sex and diagnosis at distributions are similar to those for cases in the same geographic area reported to the California State Health Department except there appears to be a somewhat smaller proportion of KPNCR patients presenting with Kaposi's sarcoma.[6] This may be an artifact due to our reliance on inpatient discharge data for diagnosis information for the majority of cases. In addition, our cases were slightly older than the AIDS patients reported to the State, whose mean age was 38.1 years.[6]

Among all 863 cases of AIDS, the median survival time was 309 days; the 25th and 75th percentiles were 103 and 552 days, respectively. The estimated probabilities of surviving one and two years (and associated standard errors) were .44 (.020) and .20 (.020). The product-limit estimates of the survival distributions for those with an initial diagnosis of Kaposi's sarcoma only, *P. carinii* only, and all others are presented in Figure 1. Diagnosis at presentation was strongly related to survival time (P = .0001). The median time to death for patients with Kaposi's sarcoma was 531 days as compared to 331 days for those with *P. carinii*. The group of AIDS patients with other diagnoses generally had the shortest survival times with a median of 187 days.

The product-limit estimate of the distributions of lifetime hospitalizations and inpatient days are presented in Figures 2 and 3. Only .5 percent of these patients had no hospitalizations. Although the majority of patients (66 percent) were hospitalized for a total of 45 days or less, there was a subset

TABLE 1—Characteristics of 863 AIDS Patients Identified at KPNCR from January 1, 1981 through June 30, 1987

	N	%
Age at Diagnosis (years)		
0–19	4	.5
20–29	110	12.7
30–39	361	41.8

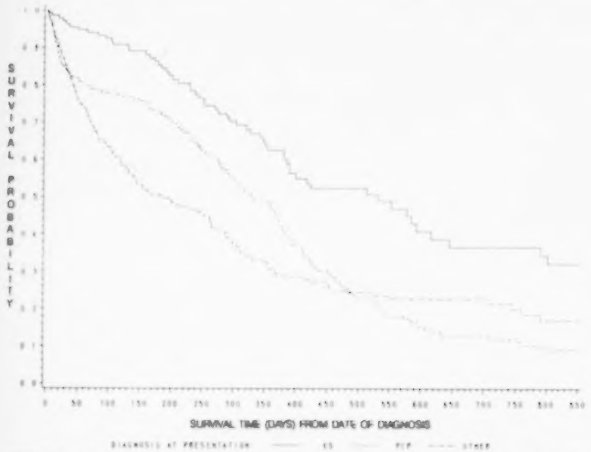

FIGURE 1—Product-Limit Estimate of the Distribution of Survival Time from Date of Diagnosis Among 863 KPNCR AIDS Patients, by Diagnosis (to provide greater detail where most of the sample falls, the distributions are truncated at 850 days).

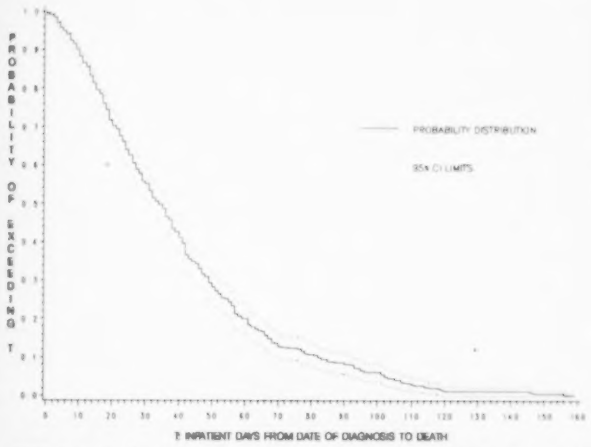

FIGURE 2—Product-Limit Estimate of the Distribution of Lifetime Inpatient Days among 863 KPNCR AIDS Patients Diagnosed between January 1981 and June 1987.

of patients that were relatively high utilizers; an estimated 8 percent were hospitalized more than 90 days. Similarly, 64 percent of the patients required three or fewer hospitalizations, but 8 percent required seven or more.

The distributions of lifetime hospital utilization for all AIDS patients by diagnosis, age, and date of diagnosis are summarized in Tables 2 and 3. The mean number of hospitalizations was 3.3, corresponding to mean and median inpatient days of 40.3 and 34. The distribution of lifetime inpatient days differed among diagnosis groups; those presenting with Kaposi's sarcoma had a lower median number of days compared to those with *P. carinii* and all others. Diagnosis at presentation, however, did not appear to be related to number of hospitalizations. Older AIDS patients experienced fewer hospitalizations but did not differ from younger patients in their inpatient days. Year of diagnosis was not related to either lifetime number of hospitalizations or days hospitalized.

Average length of stay and utilization rates are presented

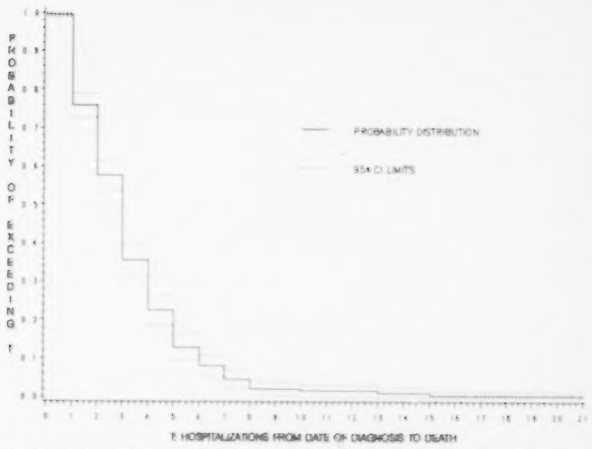

FIGURE 3—Product-Limit Estimate of the Distribution of Lifetime Hospitalizations among 863 KPNCR AIDS Patients Diagnosed between January 1981 and June 1987.

in Table 4. During 1981 through 1983, we observed 105 hospitalizations and 1,767 inpatient days in 32.9 person-years of follow-up on 58 cases, corresponding to utilization rates of 3.2 hospitalizations and 53.7 inpatient days per person-year. Based on 150.1 person-years of follow-up in the first six months of 1987, the hospitalization and inpatient day rates had declined during 1984 through 1986 to 2.6 and 31.1 per person-year, respectively. Similarly, the average length of stay per AIDS-related admission declined from 17.23 days for admissions in 1981, 1982, and 1983 to 10.69 days during the first six months of 1987.

Discussion

Our estimate of mean lifetime inpatient days is substantially lower than the 168 days reported by Hardy, *et al*,[4] and in fact is among the lowest of current estimates as summarized by Bloom and Carliner.[1] Our estimates, however, confirm the finding of other researchers that AIDS patients are hospitalized less often in the San Francisco Bay Area than in other regions of the United States. Scitovsky, *et al*,[3] suggested that strong community-based social support services in San Francisco tend to prevent or shorten hospital stays. They also suggested that in other regions there may be a larger proportion of intravenous drug users, who lack the social support network that other patients with AIDS have developed.

Diagnostic information was obtained from inpatient discharge data for 59 percent of the cases, and thus, there is some misclassification with respect to both date of diagnosis and diseases at presentation. Our estimate of the distribution of survival time from date of diagnosis to death and our utilization analysis by diagnosis subgroup are therefore less reliable than estimates obtained using complete diagnostic information from medical records on all patients. Nevertheless, our survival estimates are in general agreement with other reports from San Francisco.[15] Since it is likely that AIDS patients would generally not be hospitalized without an AIDS-related diagnosis, our primary analyses of inpatient utilization are probably minimally biased by this diagnosis date misclassification.

We examined lifetime hospital utilization among AIDS patients with well-known statistical methods usually used to

TABLE 2—Distribution of Lifetime Inpatient Days among 863 KPNCR AIDS Patients, by Diagnosis at Presentation, Age, and Year of Diagnosis

	N	Median (25th, 75th Percentile)	Mean (S.E.)

analyze time to an event. These estimation procedures properly account for the problem of not observing all patients to their deaths. Excluding patients who have not died results in a sample that is biased toward the utilization levels of shorter-lived individuals. Among the patients who died as KPNCR members, the mean number of hospitalizations and inpatient days are 2.6 and 34.6, compared to the product-limit estimates of 3.3 and 40.3; restriction of our sample to the deceased results in a 21 percent reduction in the estimate of mean lifetime number of hospitalizations and a 14 percent reduction in estimated mean inpatient days. Our estimate of the mean lifetime hospital days based on the deceased is extremely close to Scitovsky's[3] estimate of 34.7, which is obtained from a sample of deceased AIDS patients receiving care at San Francisco General Hospital, indicating that the inpatient utilization of the KPNCR patients is similar to that of other AIDS patients in the region.

Our estimates are based on utilization patterns observed only through June 30, 1987. As new therapies are introduced or as patient population characteristics change, our estimates of lifetime utilization may need to be revised. For example, improving survival rates may lead to a change in the inpatient utilization distribution. In this study, there was no evidence of a change in lifetime utilization by year of diagnosis (Tables 2 and 3), although there was a fairly strong downward trend across calendar time in utilization intensity as measured on a person-year basis (Table 4). There was a general increase in survival rates through calendar time. For those with Kaposi's sarcoma, the one year survival rate increased from .60 for those diagnosed in 1981 through 1983 to .65 for those

TABLE 4—Average Length of Stay and Inpatient Utilization Rates among 863 KPNCR AIDS Patients

Admission Date	Average Length of Stay	Observed Person-Years	Number of Hospitalizations* (per person-year)	Inpatient Days** (per person-year)
1/81–12/83	17.23	32.91	3.19	53.69
1/84–12/84	13.78	60.96	3.58	47.68
1/85–12/85	13.56	133.96	3.13	42.67
1/86–12/86	11.72	216.88	2.82	31.43
1/87–6/87	10.69	150.15	2.62	31.10

*Classified according to the date of admission.

diagnosed in 1986. For those without Kaposi's sarcoma, the one year survival rate increased from .37 for those diagnosed in 1981 through 1983 to .43 for those diagnosed in 1986. This suggests that the constancy in lifetime utilization while utilization intensity decreased can be explained in part by an increase in survival rates in recent years, i.e., as a group, the same amount of utilization was spread over a longer time period. Also, there appears to be a shift in inpatient utilization from the time near date of diagnosis toward the time of death. Given no change in lifetime utilization, this would result in declining measures of annual utilization intensity during years with less follow-up time close to death than to diagnosis.

Although not presented here, the dependence of utilization on treatment modalities, diagnostic category, and other factors could be examined using methods for regression analysis of survival data.[9,10] In summary, survival analysis methods are appropriate for examining health services utilization in groups of patients with incomplete follow-up. These methods are also useful in estimating the monetary cost of illness with censored data,[6] and an ongoing study of a random sample of KPNCR AIDS patients will examine costs associated with both inpatient and outpatient care.

Family Access to Health Care: Report Available

Family access to health care is discussed in the report of a conference held in May 1988 at the University of South Carolina and sponsored by the Health Resources and Services Administration.

Single copies of the 136-page report, *Empowering Families for Better Health,* are available from the National Maternal and Child Health Clearinghouse, 38th and R Streets, NW, Washington, DC 20057; tel: 202/625-8410.

Commentary

A Ten-Year Experience in Control of Poliomyelitis through a Combination of Live and Killed Vaccines in Two Developing Areas

THEODORE TULCHINSKY, MD, MPH, YEHIA ABED, MD, MPH, SAID SHAHEEN, MD, NADIM TOUBASSI, MD, YITZCHAK SEVER, MD, MICHAEL SCHOENBAUM, BA, AND RACHEL HANDSHER, MSc

Abstract: We describe a successful program of poliomyelitis control using a combination of killed and live polio vaccines over a 10-year period in two developing areas, the West Bank and Gaza, adjacent to a relatively developed country, Israel. During the 1970s, immunization using live trivalent oral polio vaccine (OPV) in these areas covered more than 90 percent of the infant population. Nevertheless, the incidence of paralytic polio continued to be high, with many cases occurring in fully or partially immunized persons. It was thought that this could be due to interference with OPV take by other enteroviruses present in the environment due to poor sanitary conditions in these areas. A new policy combining five doses of OPV with two doses of inactivated polio vaccine (IPV) was adopted and implemented in 1978. In the 10 years since then, immunization coverage of infants increased to an estimated 95 percent and paralytic poliomyelitis has been controlled, despite exposure to wild poliovirus from neighboring countries including an outbreak in Israel in 1988. This experience suggests that wide coverage using the combination of IPV and OPV is an effective vaccination policy that may make eradication of polio possible even in developing areas. (*Am J Public Health* 1989; 79:1648–1652.)

Introduction

The West Bank is located between Israel and Jordan, and Gaza lies between Israel and Egypt (see map). Israel has governed these areas since June 1967. Prior to that, the West Bank was administered by Jordan, and Gaza was under Egyptian rule. In 1988, the Palestinian population of the West Bank was estimated at 887,000, and that of Gaza was 600,000.[1–4] Population density in the West Bank is about 155 residents per square kilometer, and in Gaza about 1,570.[1–4] Approximately 12 percent of the West Bank population, and 53 percent of the Gaza population, live in refugee camps.[2]

Both the West Bank and Gaza are developing areas. In 1987, per capita gross national product was $2,090 in the West Bank and $1,486 in Gaza (up from $836 and $605, respectively, in 1975). In 1987, the crude birth rate in the West Bank was 41 per 1,000 population, while the Gaza birth rate was 48/1,000. In both areas, about half the population is under age 16.[4] Sanitary conditions have improved steadily over the years but still vary widely, with open sewage drainage remaining a problem in Gaza refugee camps.[4,5]

Persistence of Poliomyelitis

In the early 1970s, the Government Health Services in both areas established an expanded childhood immunization program as a major priority. This included four feedings of oral polio vaccine (OPV) in the first year of life.[4–9] By 1975, 85 percent of infants were receiving polio vaccinations, and by 1977 coverage had exceeded 90 percent.[5,7,8] Despite this, however, there continued to be many cases of paralytic polio throughout the 1970s, with many of these cases occurring in children who had received at least one, and up to four, doses of OPV. In Gaza in 1976, half of the 77 polio cases had been fully immunized with OPV, as had eight of 13 cases in 1977.[5]

In response to this problem, a review of polio policy was undertaken in 1978 by the Government Health Services. Vaccine failure was first thought to be due to a deficient cold chain, but testing indicated that the vaccine used in the field was adequately potent.[5,8–10] Diarrheal diseases were widespread, and it was then felt that these might be interfering with OPV take.[5,7,8] It was decided to modify the immunization program to include a combination of inactivated polio vaccine (IPV) and OPV for both the West bank and Gaza, in addition to emphasizing increased immunization coverage and cold chain integrity.[4–6]

Combined OPV/IPV Policy

Since 1978, IPV has been given in the West Bank in combination with diphtheria-pertussis-tetanus vaccine (DPT) in two doses, at 3-1/2 months and 5 months, in addition to five feedings of OPV, given at 2, 3-1/2, 5, 6-1/2, and 12 months. In Gaza, OPV (type I only) is given at age 1 month, followed by IPV and OPV given together at 2-1/2 and 4 months, and OPV alone at 5-1/2 and 12 months. During 1987–88, adequate supplies of IPV were unavailable, and OPV only was used.

Immunization has reached 95 percent of the infant population in both areas, as indicated by immunization data and by serosurveys.[4,8–11] Vaccinations are given through clinics, village health rooms, and mobile services by the Government Health Services, and through United Nations Relief and Works Agency (UNRWA) clinics, which provide primary health care to residents of refugee camps in both areas. UNRWA has followed the combined immunization policy in Gaza; in the West Bank, where UNRWA provides care for only 12 percent of the total population, UNRWA gives OPV alone.

Cases and suspected cases of paralytic polio are hospitalized and reported to public health officials. There is a high

level of awareness of polio in the medical and general community, and cases are likely to be reported.[4–6] All suspected cases are investigated clinically and with serial laboratory tests carried out at the Central Virus Laboratory of the Israel Ministry of Health. This includes serum antibody levels and stool cultures. Confirmation of cases is based on clinical data, stool cultures, and demonstration of antibody levels increasing over time.[5]

Polio Control

Figure 1 shows annual incidence rates over the 1968–88 period. Both the West Bank and Gaza experienced a decline in polio cases and incidence rates since 1980. During the period 1968–77, Gaza averaged 41.5 cases per year (incidence rate of 10.6 cases/100,000 population). A dramatic decline in polio incidence began in 1978: average cases per year dropped to 7.4 and 0.6 in the subsequent five-year periods (incidence rates of 1.6 and 0.1/100,000, respectively), with one case in 1988. In the West Bank, polio cases averaged some 20 cases per year (3.2/100,000) in the period 1968–77, and began to decline in 1980. There were an average of eight cases per year between 1978–82 (1.1/100,000) and then two cases per year in the 1978–82 period (0.3/100,000), with two cases in 1988.

During 1968–82, Israel averaged 13 cases of polio per year (average annual incidence rate of 0.4 cases/100,000 population). This fell to an average of 1.6 cases per year between 1983–87 (0.04/100,000), but there were 15 cases in 1988 (Table 1).

Table 2 shows a summary of various serosurveys for polio antibody levels carried out in the West Bank and Gaza.[6,8–9,12–14] While the serosurveys did not group children by vaccination status, high levels of immunity in the latter years are due primarily to increased vaccination coverage and improved seroconversion rather than to circulation of wild polio virus, since the incidence of polio decreased during this time.

The 1988 Israel Polio Outbreak

Since 1963, Israel's national routine immunization policy for polio has been to vaccinate infants with four feedings of OPV only. The continued occurrence of endemic polio during the late 1970s, mainly concentrated in five of 15 subdistricts, led to the institution since 1978 of annual spring booster campaigns using type I OPV among all children ages three years and younger in selected areas of these subdistricts.[12,13] Total reported coverage of polio immunization in Israel is over 90 percent.[12–14]

In two other subdistricts in Israel (with 6.7 percent of the total population in 1986), a trial program of three doses of IPV only was carried out between 1982–88.[6,12–14] In 1988, an outbreak of 15 cases of type I poliovirus occurred in Israel; 12 of these cases were from one of the subdistricts (Hadera) using IPV alone. These were largely concentrated in areas of this subdistrict that had serious sanitation problems. The other three cases were temporally and virologically associated with the outbreak, but there was no confirmed physical contact with Hadera. Nine of the 15 cases were 15 years of age or older; nine had received at least three doses of OPV in the past. This outbreak has been described in detail.*[15–17]

The West Bank and Gaza are not immediately adjacent to each other. However, the distances between the most populated areas of the West Bank, Gaza, and Israel average under 50 kilometers. There is very extensive contact between the populations of all three areas (Figure 2).

Despite this, the population of the West Bank and Gaza was unaffected in the 1988 Israel outbreak, although one of the two polio cases in the West Bank may have been epidemiologically connected to the Israeli outbreak. The other case was vaccine associated.** The one case in Gaza in 1988 was epidemiologically unconnected. However, in view of the risk of spread of the disease from Israel to the West Bank and Gaza, a program of administering a booster dose of trivalent OPV to everyone aged 0–40 was carried out, in conjunction with a similar campaign in Israel. This program reached approximately 90 percent of the target population in the West Bank and Gaza.***

The OPV/IPV Debate

The debate on polio policy has been primarily between the Sabin[18] and Salk[19,20] schools who advocate, respectively, OPV-only and IPV-only vaccination policies. The 10-year experience of the West Bank and Gaza reported here suggests that a combined IPV/OPV program can result in polio control even in developing areas with significant sanitation problems and with high potential for the import of wild virus from neighboring areas where wild polio virus is still prevalent.[21]

Oral polio vaccine (OPV) is relatively inexpensive and easy to administer. It induces both humoral and intestinal immunity (secretory antibody response). Due to its oral administration and consequent presence in the intestinal system, it diffuses immunity directly through contact with the vaccinee, and indirectly through the environment, especially in areas with relatively unsanitary conditions.[18,22–29] OPV-induced immunity among contacts of the vaccinee and through the environment is a major advantage over using IPV alone.[25,27]

Israel					
Cases	53	67	77	8	15
Average annual cases	10.6	13.4	15.4	1.6	—
Average annual incidence rate	0.3	0.4	0.4	0.04	0.34

NOTE: Incidence rates are cases per 100,000 population.

TABLE 2—Serosurveys for Percent with Protective Antibody Levels by Polio Type, West Bank and Gaza

Area/Age Group	Year	No.	Type I	Type II	Type III
Gaza					
6–36 months	1974	50	56%	74%	66%
	1978	50	60	82	70
	1980	117	100	98	100
	1983	209	89	83	82
West Bank					
6–8 years	1983	240	92	96	97
7 years	1986	266	97	99	96

NOTES: Serosurveys were performed with 1:4 dilutions (1974 in Gaza used 1:10). Survey samples were random (1980 in Gaza was follow-up survey of vaccinees only).

However, successful immunization with OPV requires four doses at appropriate intervals. In addition, because OPV contains an attenuated live virus, there are rare cases (1 per 2.6 million doses in the United States for 1974–84) of vaccine associated disease, in which the vaccinee or a person in contact with the vaccinee incurs paralytic polio from mutated vaccine virus.[22,25,27,30–31] Additionally, there is strong evidence that OPV take is inhibited if the vaccinee is infected with other enteroviruses, resulting in failure of the vaccine to produce satisfactory levels of protective antibodies.[23,24,26,31]

Inactivated polio vaccine (IPV) rapidly produces a high level of protective antibodies. It poses no risk of vaccine-associated disease, and is not susceptible to interference from other enteroviruses.[26] IPV also protects vaccinees (although not necessarily their contacts) from vaccine-associated disease contracted from OPV doses administered subsequently.[25–27] Newly developed enhanced-potency IPV vaccines are even more effective in terms of speed and level of immunogenicity than previous inactivated vaccines.[22,24]

However, IPV produces only limited intestinal immunity. This permits vaccinees who receive only IPV to be acute carriers of polio. The wild polio virus can enter and infect the intestinal tract of vaccinees, who will not themselves contract paralytic polio, but may excrete the virus, spreading it through the environment or directly to other people.*[25–27]

The Combined OPV/IPV Approach

Both vaccine types have proven effective in controlling

FIGURE 2—Map of Israel Showing West Bank, Gaza and Hadera (site of 1988 outbreak)

*Melnick JL, Orenstein WA, Rey M: Op Cit.

polio in developed and developing countries. However, particularly in less than ideal sanitary conditions, neither type used alone seems capable of eradicating the disease. Recently, the combination policy of IPV and OPV administered sequentially has attracted interest internationally.[22,26–27,32–33] Denmark has been using such a policy successfully since 1968.[27,32]

Although poliomyelitis is an acute viral disease affecting humans only, with no animal host and no chronic carrier status, it can be imported by infected persons from outside a given geographical area. Polio virus can then be transmitted by contact or through sewage and waste processing systems.

Developing countries often face great difficulties in vaccinating the numbers of people necessary for adequate herd immunity. In addition, they face problems of interference with vaccine take from other enteroviruses. The policy of combining OPV and IPV is well suited for minimizing the effects of these problems.

As the 1988 polio outbreak in Israel illustrates, an IPV-only vaccination policy for areas with sanitary problems, and where wild polio virus is present, has potential for failure. The 1985 polio outbreak in Finland, even though associated with an inadequately immunogenic IPV (for type 3), further suggests that an IPV-only policy may not produce adequate levels of herd immunity even in areas without serious sanitary problems and where wild polio virus introduction may be unlikely.[21,28] In Holland, where IPV has been used alone, repeated introductions of wild polio virus were associated with relatively large numbers of cases (114 over the period 1974–84), mostly among non-immunized members of religious communities. Introduction of wild polio virus to an area by travelers to and from developing areas is a risk factor that must be considered when determining polio vaccine policy.[25]

The spread of immunity through personal and environmental contact from OPV use is a major advantage; the reduction or elimination of vaccine-associated polio by use of IPV is also a major advantage. The West Bank and Gaza experience show the effectiveness of combining IPV with OPV in areas where OPV alone has a high failure rate.

The combined policy has the further advantage of at least partially mitigating the problem of incomplete vaccination schedules. Giving OPV and IPV at the same time makes it likely that infants, particularly in populations where return visits for further vaccinations cannot be guaranteed, will be protected even after only three visits although a complete schedule is more desirable. The new, high potency IPV's ability to rapidly create high levels of protective antibodies makes seroconversion more likely, even with incomplete vaccination schedules. In the applied field setting, the combined policy can lend itself both to routine campaigns and to the blitz campaign approach used in some developing countries.[24,31,34]

In addition, the combined IPV/OPV policy can reduce or eliminate the risk of vaccine-associated polio, which remains an important factor in the epidemiology of the disease. As an example, four of the eight Israeli polio cases occurring between 1982 and 1987 were vaccine-associated, even though the rate of vaccine-associated polio reported in the United States is considerably lower. For this reason, IPV should be given before or with the first OPV dose, since the greatest danger of vaccine-associated disease comes from the first dose of OPV in individuals previously unvaccinated against polio.[29]

International Implications

The global eradication of smallpox was an outstanding achievement, with enormous benefit to the world. It was achieved by a combination of a safe, effective vaccine, new technology in vaccination, a world consensus on the need to act, and excellent strategies in application of the technologies available.[23] As the World Health Organization (WHO) now has targeted polio for eradication, it is vital to develop the most appropriate strategies in the use of existing and new technologies. Polio eradication will be more complex than was smallpox eradication because of differences in transmission, clinical manifestation, interference, and duration of immunity. Perhaps most importantly, immunity to polio requires multiple doses and boosters, whereas a single dose of smallpox vaccine confers lifelong immunity.[23]

As a result of the importance and complexity of the issue, documented field trials of various approaches to polio control are needed. The West Bank and Gaza experience in use of the combined OPV-IPV approach should be considered for replication in wider field trials in the search for appropriate strategies in polio control/eradication, particularly for developing countries. The Israel Ministry of Health has recently decided to adopt the combined OPV/IPV approach for its future immunization policy. Although the combined approach is more expensive than OPV alone, its advantages make the combined approach an essential tool in the world battle to eradicate polio.

ACKNOWLEDGMENTS

We wish to acknowledge the important contribution to this work by Prof. Joseph Melnick of Baylor Medical School, Houston, Texas; Prof. Natan Goldblum, Virology Department, Hebrew University Faculty of Medicine; Prof. C.H. Gerichter, former Director of Public Health Laboratories, Israel Ministry of Health; Dr. Eli Lasch, former Chief Medical Officer, Gaza; Mrs. Zilla Acker and Mr. Micha Blum, Government Health Services, Judaea and Samaria (West Bank); Dr. Samir Badry, Medical Director, UNRWA, Gaza; as well as the Palestinian staff of the UNRWA and Government Health Services in the West Bank and Gaza. We also wish to thank Dr. P.E. Slater and Dr. C. Costin, Epidemiology Department, Israel Ministry of Health, for their assistance. The 1986 serosurvey on the West Bank was in part sponsored by the World Health Organization.

Business and Nursing Schools Join Ranks to Develop MBA-MSN Degree Programs

Ten of the nation's top-rated graduate schools of business are joining ranks with their graduate schools of nursing to provide future nursing leaders with the same caliber of management, financial, and analytic training usually reserved for the business world. Superior management skills—combined with their clinical skills—are essential to tomorrow's nurse leaders. This unprecedented alliance between the schools of business and nursing "to develop joint MBA-MSN degree programs comes in recognition of the enormous resource allocation, quality control, and employment practice decisions now made by nursing leaders," said Dean Meyer Feldbert of Columbia University Graduate School of Business.

Nursing comprises the largest workforce in the health care industry, and health care is the nation's third largest industry, with expenses approaching $2 billion per day.

Almost 300 nurses with MBA degrees were recently surveyed for The Commonwealth Fund by Louis Harris and Associates, which found that most nurse-MBAs get far more managerial responsibilities as a result of their MBA degree. The most valued skills, according to the nurse-MBAs surveyed, were in finance and marketing. Eighty-eight percent of respondents advised other nurses like themselves to get an MBA degree.

Each of the universities developing the new joint degree programs will receive $100,000 in start-up support from The Commonwealth Fund. The Fund will also provide fellowships of $15,000 each to 25 nurses per year, as further encouragement of this type of education.

The 10 universities developing MBA-MSN graduate degree programs are: University of California (Los Angeles), Case Western Reserve University (Cleveland), Columbia University (New York City), Iowa University (Iowa City), University of Michigan (Ann Arbor), University of Rochester (New York State), Rush University/Northwestern University (Chicago), University of Texas (Austin), Vanderbilt University (Nashville), and University of Virginia (Charlottesville). Courses are due to start in Fall 1990.

The Commonwealth Fund is located at Harkness House, One East 75th Street, New York, NY 10021. Tel: 212/535-0400.

A Comparison of Perceived and Objective CVD Risk in a General Population

Minoo Niknian, PhD, Sonja M. McKinlay, PhD, William Rakowski, PhD, and Richard A. Carleton, MD

Abstract: This report examines correspondence between perceived and objective (American Heart Association's RISKO) risk of heart attack and stroke in a randomly selected sample from two surveys (n = 4,171) conducted in each of two New England cities, in 1981–82 and 1983–84, respectively.

Results confirmed prior reports that people tend to underestimate their CVD (cardiovascular disease) risk and showed that estimates of those at lowest risk were most accurate. (*Am J Public Health* 1989; 79:1653–1654.)

Introduction

Self-assessments of health status have been an integral part of behavioral science research and theory. One question of continuing interest has been the correspondence between "perceived' and "objective" indices of current health. As a general rule, self-assessed health appears to have a basis in actual physical status, using professional or laboratory indices of illness severity as a standard for comparison.[1–3] However, it also seems well-accepted that when discrepancies between personal and objective data occur, individuals are more likely to overestimate their health status.[4–6] This report examines the correspondence between perceived and "objective" risk of heart attack or stroke in a representative community sample.

Methods

Data were collected in two community health surveys, conducted in each of two New England cities in 1981–82 and 1983–84, respectively. Each spanned an entire year to control for seasonal differences. Approximately 5,244 interviews with adults 18–65 years were completed and two blood pressure readings, height, weight, total cholesterol and HDL were measured. Response rate averaged 70 percent.[7]

Two variables were used to construct the dependent variable for this analysis: *Perceived Cardiovascular (CVD) risk* and total *RISKO score* (from the American Heart Association's CVD risk assessment instrument).[8] RISKO was calculated with height, weight, blood pressure, cholesterol and estrogen (for women) as obtained directly from the surveys (n = 4,171). A second, estimated score, using the RISKO substitution rule was analyzed, produced equivalent results and is not reported here.*

RISKO ranges from 0 (lowest risk) to 24 (highest risk) for each of four age × gender groups (<55, ≥55 years; male and female). Three risk categories were constructed from this score: "low risk" was defined as having all except one risk factor at the lowest risk level for those aged <55, producing a maximum score of 5. Similarly, the "high risk" category was defined as having all factors at the third risk level or higher in the younger age category, producing a minimum score of 12. The three objective risk categories, defined on RISKO scores were therefore (0–5, 6–11, 12–24). Because RISKO is conditional on age × sex category, a score of 9 has the same relative meaning of average risk, in each age × sex group.

Perceived risk was assessed as: "Compared with persons of your own age and sex, how would you rate your risk of having a heart attack or stroke within the next five years?" The pre-coded responses were: high (3), average (2), low (1), and don't know. Persons responding to this last category (7 percent) were excluded from subsequent analyses.

Independent variables considered in this analysis were: age (in years), gender, years of schooling, ethnicity (Portuguese, French Canadian, and other), body mass index (Wgt [Kg]/hgt^2 [m^2]); smoking status (yes/no); taking any CVD-related medication (yes/no); and knowledge (whether or not at least one CVD risk factor is mentioned as modifiable).

The discrepant categories between RISKO and perceived risk have possible values (−2, −1, 0, 1, 2), where 0 represents agreement. Using this score as the dependent variable, a stepwise regression[9] was performed on all the independent variables, entering sociodemographic characteristics first. Variables were retained in the model if their individual F-values were at approximately the .01 level and/or induced a relative increase in R^2 of greater than 5 percent. An equivalent discriminant analysis, as a validity check of this approach, produced the same models.* The second stage involved calculation of weighted and unweighted Kappa statistics,[10] which measures agreement between two scoring systems, independently applied to the same subjects.

Results

As expected, educational level had a significant impact on congruence, as did age and gender. Interestingly, knowledge of CVD risk had no association with discrepant scores. Only the two well-known CVD risk factors (smoking and BMI) contributed to explaining discrepant scores, as did use of hypertension medication (diuretic or beta-blocker).

To further investigate the concordance between perceived and actual risk, Kappa statistics were calculated[10] for each level of each of the significant covariates mentioned above as well as the percent of responses in agreement. Females (44.4%) were more likely than males (40.5%), while younger people (44.3%) were more likely than those over age 44 (40.3%) to perceive their risk accurately. Education, dichotomized at 16 years, was positively related to higher agreement (47.1% compared to 42.5%). This is consistent with the regression results using the continuous measure of education. Those at lowest CVD risk [non-smokers (44.6% versus 40.0%) and those with BMI ≤22.5 (49.8% versus 40.7%)] perceived their risk more accurately, as would be anticipated. Those on hypertensive medication also perceived their risk more accurately (45.5%) than those not on medication (42.4%).

Apart from these associations, the overall Kappa was .078 which is low and never exceeds 0.12 indicating that agreement was generally poor. The direction of disagreement was further investigated (Table 1) by considering the percentage under- and overestimating their risk. From these statistics it is evident that twice as many people underestimated their risk, compared to those who overestimated their risk.

Discussion

The analyses presented here lead to two major conclusions. First, there was poor agreement between self-perceived and a more objectively assessed cardiovascular risk, with a high prevalence of risk underestimation. Second, higher levels of agreement between perceived and objective risk are associated with being female, being younger, having more education, being a non-smoker or on hypertensive medication, or having a lower than average BMI. As expected, people at low CVD risk are the most likely to correctly define themselves. Hypertensives, as the clear exception, are sensitized to their higher risk. Knowledge of CVD risk was not independently associated with increased accuracy because of its high correlation with educational level.

The results presented here confirm prior reports that people generally underestimate future risk of negative health outcomes. The important additional contributions of this study are:

- Use of a representative, randomly selected community sample of adults; and
- Use of a validated scoring system (RISKO) to assess cardiovascular disease risk within a specific future period (five years).

In this environment of heightened awareness and decreasing mortality rates, the persistence of CVD risk underestimation is of substantial concern. Clearly there is still considerable room for improvement in health education efforts, at least with respect to CVD.

hourly employees and the start of programs for salaried employees encouraging early retirement and separation from the corporation.[10] The number of inactive employees (retirees and surviving spouses) grew twice as fast as the active workforce. Dependents, who comprise over half of the GM population,[7] accounted for much of the growth. The number of spouses grew for all employee types except active salaried employees, and grew very rapidly, nearly 3.5 percent per year. In contrast, the number of children hardly grew at all.

Discussion

This is the first study to examine demographic change in a population provided health benefits by a major corporation. It has documented rapid growth, faster than in the US, in this large group. If current trends continue, this population will become larger, older, and have a greater percentage of women.

National health care utilization statistics[11–12] suggest that these demographic changes alone increased GM hospital days of care by 10 percent and physician visits by 7 percent from 1983 to 1987. Consequently, it is not surprising that GM's health care costs rose from $2.2 billion in 1983[5] to nearly $3 billion in 1987.[6]

The trends identified in this study may or may not predict future demographic conditions. Future investigations should estimate the impact on growth rates of employment conditions, sociodemographic processes influencing population growth, and administrative changes.

This study has found that despite increased employment, dependents, particularly spouses, were responsible for most of the population growth. This finding demonstrates that much remains to be learned about how individuals, particularly nonworkers, become eligible for employer-sponsored health coverage. Case studies of employers, such as this one, can illuminate findings from general population surveys about the link between employment and health care coverage.[13] In response to potential legislation that increases the cost of health benefits, employers could pay more attention to who is eligible for these benefits in their efforts to provide cost-effective coverage.

Fatal Unintended Carbon Monoxide Poisoning in West Virginia from Nonvehicular Sources

ROY C. BARON, MD, MPH, RONALD C. BACKER, PHD, AND IRVIN M. SOPHER, DDS, MD

Abstract: Based on medical examiner reports and state vital records, 1978–84, nonvehicular carbon monoxide (CO) caused 62 unintended deaths, representing 42 percent of all unintended fatal CO poisonings in West Virginia. Sources were almost always heating or cooking appliances associated with incomplete combustion of fuels (methane, butane, or propane) not commonly recognized for their potential to produce CO. Hazards included failure to provide recommended venting, neglected maintenance, or use in small areas without natural ventilation. (*Am J Public Health* 1989; 79:1656–1658.)

From the Office of Epidemiology and Health Promotion (Baron), and the Office of the Chief Medical Examiner (Backer, Sopher), West Virginia Department of Health in Charleston; and the Division of Field Services, Centers for Disease Control (Baron). Baron, MD, MPH, Division of Field Services, Epidemiology Program Office, Centers for Disease Control, Atlanta, GA 30333. This paper, submitted to the Journal February 13, 1989, was revised and accepted for publication May 18, 1989.

Introduction

Carbon monoxide (CO) is the agent most often responsible for fatal, unintended poisoning in the United States.[1] Motor vehicle exhaust causes the majority of cases, but a substantial number occur in domestic or recreational settings[1] where sources are not adequately identified in national mortality statistics[2] or by death certificate review.[3] While heating appliances are recognized as important sources of CO exposure,[3–9] their overall role and specific hazards have not been carefully examined in a population-based study.

Using data obtained principally from the Office of the Chief Medical Examiner (OCME), we have reviewed all deaths in West Virginia attributed to unintended CO exposure from nonvehicular sources during a seven-year period.

Methods

The West Virginia Medical Examiner has jurisdiction over all homicidal, suicidal, accidental, and unattended

natural deaths in the state and maintains a centralized case record file. When indicated, analyses for blood alcohol concentration (BAC) and percent carboxyhemoglobin (COHb) are performed by standard methods.[10,11]

We reviewed the files for the period 1978–84 to identify all certified unintentional deaths attributed to CO from nonvehicular sources, excluding uncontrolled fires. We also reviewed vital statistics for in-state deaths coded "accidental poisoning from gases and vapors" during 1978 (ICD-8 codes E870-7) and 1970–84 (ICD-9 codes E867-9) to identify any additional unintended, nonvehicular CO deaths not reported to the OCME. Data recorded included each victim's age, sex, BAC, and percent COHb, along with date and place of death, and the alleged CO source. Hazards identified at the site of exposure were recorded from information either in the OCME record or acquired through special request to local police or fire departments.

Results

From 1978–84, there were 62 unintentional deaths in West Virginia attributed to CO from nonvehicular sources (two were recorded by vital statistics alone). These deaths occurred in 38 domestic episodes (51 deaths) and in seven recreational settings (11 deaths). On the death certificates, 31 (50 percent) fatalities were not specifically attributed to CO and one was mistakenly associated with motor vehicle exhaust (Table 1).

Postmortem COHb was measured in 47 victims and ranged from 50–88 percent. For eight victims who were not tested, death from CO was determined by association with confirmed cases (three deaths), by CO-positive environmental samples (three deaths), or by elevated premortem COHb (two deaths). For seven remaining victims, CO was assumed the cause based on observations at the scene.

Fatal episodes increased sharply in the fall and peaked during the winter (Figure 1). The male to female victim ratio was almost 4:1 (Table 2). Death rates were highest in young adults and the elderly. Blood alcohol was tested in 40 (70 percent) of the 57 victims ≥15 years of age. Nine (22.5 percent) tested positive, with BAC ranging from 2–46 mmol/L; only three (7.5 percent) had levels consistent with legal intoxication (22 mmol/L).

Residential Settings

Furnaces or space heaters were implicated in 34 (89 percent) of the 38 residential episodes. Cooking ranges were the source of CO in three (8 percent) episodes and a generator was the source in one. Thirty-six units (94 percent) were fueled by natural gas (methane) or butane (only one unit). Table 3 shows that on-site investigations found hazards related to:

- installation of large volume furnaces dependent on direct venting of combustion products to the outside;

TABLE 3—Cause of Hazard and Fuel Responsible for Fatal Unintentional Exposure to CO from Nonvehicular Sources by Setting, West Virginia, 1978–84

Setting and Cause of Hazard	Episodes	Fuel
Residential		
Faulty installation		
Failure to install or connect vent	4	Methane (4)
Vent obstructed during installation	3	Methane (3)
Faulty vent design	3	Methane (3)
Neglected maintenance		
Burner malfunction from accumulated debris or faulty adjustment	5	Methane (4), Butane (1)
Damaged vent*	4	Methane (4)
Use in sealed or confined enclosure	13	Methane (12), Kerosene (1)
Miscellaneous	1	Gasoline (1)
Not identified	5	Methane (5)
Recreational		
Use in confined enclosure	7	Butane (2), Propane (3) Charcoal (1), Wood (1)

*Includes combustion product leakage through loose indoor vent joint (three episodes) or backflow caused by downdraft from corroded exterior vent segment (one episode).

- use of smaller units not requiring direct venting but operated in closed rooms. Windows were sealed with plastic in at least four of these 13 episodes;
- neglected maintenance.

Recreational Settings

Five recreational episodes involved the use of butane or propane-fueled heating stoves in poorly ventilated enclosures (two tents, two recreational vans, and a cellar house); one resulted from a smoldering charcoal grill in a recreational van; and one resulted from a poorly vented wood-burning fire in an enclosed outdoor shelter.

Discussion

Despite the elimination of CO from domestic gas since the 1940s and '50s with conversion to natural gas, and the widespread use of other clean burning fuels, domestic and recreational CO exposure remains an important health hazard in West Virginia, contributing 62 (42 percent) of the 149 unintended CO deaths from 1978 through 1984; 87 deaths from motor vehicle exhaust were described earlier.[12] Alcohol use was not a common predisposing factor in these exposures as it was for exposures to motor vehicle exhaust. For surveillance purposes, coded death certificates alone grossly underestimate the problem in nonvehicular settings.

While each of these episodes reflects some failure to adequately remove CO from the living or recreational environment, the vast majority are associated with fuels not commonly recognized for their potential to produce CO.[13] Unlike cruder fuels (gasoline, kerosene, wood, and coal), methane, butane, and propane normally undergo complete combustion in the presence of sufficient oxygen, producing nontoxic carbon dioxide and water vapor.[14] In most instances, CO production by these fuels had at least one obvious explanation:[14]

- operating small volume, unvented gas-burning heaters in closed spaces without natural ventilation (e.g., open windows) for replacing depleted oxygen;
- inadequate venting (removal) of combustion products, displacing oxygen from the ambient supply and/or preventing adequate air flow to the burners. While this was usually associated with faulty installation, it occasionally reflected long-term use and neglected maintenance;
- neglecting to adjust or clean burners, causing inadequate mixing of oxygen and fuel in the combustion chamber.

Prevention therefore depends largely on assuring proper function and appropriate use of gas-burning applicances and can be achieved by professional installation, annual servicing, and education to avoid burning fuels in confined or tightly sealed enclosures. A coordinated educational and inspection program involving health departments, gas companies, and appliance distributors—conducted in the late summer and early fall—would be desirable. Because there is a tendency to conserve heat by closing or sealing windows, terminating the production of unvented units has also been suggested.[7]

Nonlethal CO exposure is a significant health hazard[4,6,7] that can be overlooked when symptoms of headache, nausea, vomiting, and malaise are attributed to other conditions. Several reports of fatalities among persons who had previously consulted a physician[8,9,13] suggest that health care providers can help to identify homes with a CO hazard by recognizing symptoms of exposure.

Gastrointestinal Effects of Water Reuse for Public Park Irrigation

ROGER DURAND, PHD, AND GERHARD SCHWEBACH, MS, MPA

Abstract: To investigate the gastrointestinal effects of employing recycled water as an irrigation source for urban public parks, we studied subjects active in parks irrigated with potable water, nonpotable water of wastewater origin, and nonpotable water of runoff origin. Wet grass conditions during activity and elevated densities of common indicator bacteria, but not exposure to nonpotable irrigation water per se, were found associated with an increased rate of gastrointestinal illness. (*Am J Public Health* 1989; 79:1659–1660.)

Introduction

Water reuse or recycling has become a widely practiced solution to the water shortage problems of arid and semi-arid regions of the United States.[1–3] To date, however, there is almost no evidence available on the health effects of using recycled water as an irrigation source for public access parks.[4] This paper reports the results of an investigation of the gastrointestinal consequences of employing recycled water for irrigating urban parks. The investigation itself, conducted in the city of Colorado Springs over the period from 1984 to 1987, was designed to answer three research questions:

- Does the irrigation of public access parks with recycled nonpotable, rather than potable, water result in a greater incidence of reported gasrointestinal illness among park users?
- Do higher degrees of exposure to nonpotable water used in irrigation lead to an increased incidence of reported gastrointestinal illness among park users?
- Can an indicator bacteria and bacterial density that is associated with an increased rate of gastrointestinal illness be identified?

Methods

In order to address the research questions, a prospective cohort research design was utilized. Epidemiologic data were collected by means of telephone surveys over two irrigation seasons from randomly selected subjects active in parks irrigated with potable water, nonpotable water of wastewater origin, and nonpotable water of runoff origin. The nonpotable water of wastewater origin utilized for park irrigation was effluent that had been sand-anthracite filtered and chlorinated up to a level of 4–6 mg/L. The nonpotable irrigation water of runoff origin was untreated city runoff that was collected in a pond.

During an initial interview, conducted within two days of park activity, each subject's presence in a park at the scheduled time was confirmed. Each research subject was then asked a battery of questions concerning his/her park activity and exposure to the park's irrigation water. The same subjects were contacted again 10 to 12 days later to determine whether they had experienced an illness in the intervening time period and, if so, the nature of the symptoms they experienced. Following studies sponsored by the Environmental Protection Agency (EPA),[5] "credible symptoms" of gastrointestinal illness were studied as the principal dependent variable. Such symptoms were defined to include reports by subjects of any one of the following accompanying "stomach discomfort": diarrhea, vomiting, cramps, fever, weight loss, excessive gas, or blood in stools.

A total of 2,642 subjects were surveyed on both the initial and follow-up interviews for a completion rate of 94 percent among those potential subjects who could be contacted. Unsuccessful attempts were made to contact an additional 511 subjects. All subjects were screened to avoid including them in the study more than once.

In addition to the survey evidence, microbiological samples of irrigation water were collected periodically in the parks included in the study that were irrigated with nonpotable water. A few samples were also obtained from parks employing potable irrigation water. Analyses were performed on these samples both for common indicator bacteria and for the biological pathogens *Salmonella* and *Shigella* using standard methods of microbial analysis.[6]

Results

Adjusted for the effect of gender, subjects exposed either to wastewater or to run-off water reported credible symptoms of gastrointestinal illness (6 percent and 5 percent, respectively) about as frequently as subjects exposed to potable irrigation water (7 percent) (Table 1). Unadjusted rates for respondents active in parks irrigated with potable water were higher than among counterparts active in parks irrigated with wastewater and runoff at statistically significant levels, but adjustments for variations in the gender and age composition of the parks clientele eliminated this initial difference. Separate controls for type of park activity (soccer and flag football versus golf, softball, and senior citizen games) and for variations in degree of exposure to irrigation water (wet grass, sprayed by a sprinkler, frequency of prior exposure and length of exposure) did not reveal a greater relative incidence of reported symptoms among subjects exposed either to wastewater or to runoff.

Interestingly, wet grass conditions during activity, regardless of type of park irrigation water, were found associated with greater symptoms reporting (adjusted difference = 3%, 95% CI = 1, −1), a finding consistent with some previous research.[7]

To eliminate the effect of interpark mobility or "park switching," we examined the 105 individuals from parks irrigated with potable water who had participated in an activity in a park irrigated with nonpotable water prior to the follow-up survey. The reported rate of illness was the same as in the remaining 966 subjects who did not switch.

Subjects active in parks irrigated with runoff water were found to be exposed to higher average (mean) densities of fecal streptococci, fecal coliforms, and total coliforms than were other subjects. The mean fecal streptococcus and the

*Rate adjustment based on characteristics of total sample.
Gender: male (69), female (31).
Age: 0–15 years (19), 16–65 years (73), over 65 years (8).
Park activity: golf, softball, senior games (74), flag football, soccer (26).
Grass conditions: wet (40), dry (60).
Sprayed: yes (4), no (96).
Prior exposure: frequent (38), infrequent (62).
Length of exposure: less than 3 hours (63), more than 3 hours (37).

mean fecal coliform densities for subjects exposed to wastewater irrigation never exceeded 11.9/100 mL and 5/100 mL, respectively, while those for subjects exposed to runoff exceeded 12,000/100 mL and 3000/100 mL, respectively, in one study year. Similarly, total coliform counts per 100 mL averaged as high as 150 in one year for subjects in parks irrigated with wastewater compared to 60,000 for their runoff counterparts in one of the years. The densities to which subjects active in parks irrigated with potable water were exposed were a constant zero value.

Among subjects exposed to either wastewater or runoff irrigation, the percentage of symptom reports was found to be greater among those active in a park when the 500/100 mL fecal coliform density level was exceeded than when it was not exceeded (Table 2). Identical results were obtained for fecal streptococci at the 500/100 mL level and for total coliforms at the 3,000/100 mL level. Symptom reports were not found to differ significantly at any other bacterial density.

TABLE 2—Credible Symptom Reports by Fecal Coliform Counts/100 mL

	Under Count		Over Count

200	4	37/922	6	28/439	2	0,4
500	4	37/953	7	28/427	3	1,5
3,000	4	46/1066	6	19/314	2	−1,5

Discussion

These results suggest the utility of fecal coliforms, fecal streptococci, and total coliforms at the identified density levels (500, 500, and 3000 per 100 mL, respectively) in establishing health standards for public park irrigation. Second, they suggest the advisability of park management practices that minimize the exposure of park patrons to wet grass conditions. And finally, they suggest that recycled water can be used for public park irrigation without undue hazard to health, provided that bacteria density levels are kept below those identified here.

ACKNOWLEDGMENTS

The investigation reported in this paper was funded by the Wastewater Division, City of Colorado Springs, Colorado, and conducted in cooperation with the El Paso County (Colorado Springs) Health Department and the State of Colorado Department of Health.

New from nchs

First Births to Older Mothers, 1970–86

STEPHANIE J. VENTURA, AM

The number of first births to women in their thirties has quadrupled in the 16 years, 1970–86.[1] Throughout the 1970s, the increases were largest for women ages 30–34 but, since 1980, the increases in first births and first birth rates have been much larger for women ages 35–39.[1]

In 1986, 181,504 women ages 30–34 gave birth to their first child, more than four times the number (42,404) reported in 1970. Although the typical ages of childbearing continue to be 15–29 years, women in their early thirties accounted for 12 percent of all first births in 1986 compared with just 3 percent in 1970. The rise in first birth rates for these women has been nearly as impressive: 17.5 births per 1,000 women ages 30–34 in 1986 compared with 7.3 in 1970. Increases for women 35–39 were also substantial, although the numbers are considerably smaller. The rate for these women increased from 2.1 to 4.7 during this period (Table 1).

These findings are among those included in a recent report from the National Center for Health Statistics (NCHS) which also includes information on demographic patterns such as educational attainment and marital status of the mother and maternal and infant health characteristics.[1] The data are drawn from the live birth certificates of all States and the District of Columbia.

The increases during the early 1970s in first-time childbearing by women in their thirties occurred at the same time that there were steep reductions in higher order birth rates or, to put it another way, a decline in large families for older women. In the five years from 1970 to 1975, rates for fourth and higher order births for women aged 30 years and older fell by about one-half. As a consequence of these declines, which more than offset the slowly increasing first birth rates, the overall birth rate for women in their thirties dropped during the 1970s (Figure 1).

The reversal of these declines beginning in the mid-1970s is associated entirely with the sizable increases in first-birth rates, while higher order rates continued to decline but at a much slower pace. Higher order births comprised only 20 percent of all births to women aged 30 and older in 1986 compared with 55 percent in 1970.

The dramatic increases measured since 1970 in first-time childbearing by women aged 30 and older could have been anticipated because of several important demographic trends. First, there has been the widespread postponement of marriage by young people and the growing rate of dissolution of their marriages.[2,3] Thus, in 1986, 36 percent of women ages 25–29 years were not married (i.e., never married, widowed, or divorced) compared with 15 percent in 1970.[3]

A second important change has been the sharp decline and then leveling off in first birth rates for women in their twenties, particularly well-educated women, leaving large numbers and proportions of women still childless at age 30 and older. Between 1970 and 1975, first birth rates for women in their early twenties declined by nearly one-third; among women who were college graduates the rates fell by one-half. Some of this decline was made up for by small increases in birth rates for women ages 25–29. But the rates for women ages 25–29 stabilized by the late 1970s and, for college graduates, the rates have fallen since 1980. Because of these changes, large numbers and proportions of women have reached age 30 without having had any children. One-fourth of women ages 30–34 in 1986 were childless compared with 12 percent of comparably aged women in 1970.

A third important factor is the substantial growth in the number of women ages 25–39, from 18.4 million in 1970 to 30.9 million in 1986, a 68-percent increase.[4,5] These women, now ages 25–39 years, were all born in the baby boom years following World War II.

Fourth is the fact that national surveys show that most women intend to have at least one child; only about 10 percent of women in their early thirties expect to remain childless.[6]

Because of the interaction of these demographic patterns it was perhaps inevitable that the first birth rates for women in their thirties would surge upward in the late 1970s and 1980s. That is what has happened.

The educational attainment of women who became mothers at relatively older ages has dramatically increased; a larger proportion of these women than of women in any other age group has completed college. Since 1980, close to half of the women in their thirties having their first child were college graduates, compared with one-fourth of comparable women in 1970 (Figure 2). Birth rates specific for educational attainment provide further evidence that the postponement of childbearing and the making up of delayed first births have been primarily confined to well-educated women. For example, the first birth rate for college graduates ages 20–24 fell from 81 in 1970 to 29 in 1985, and for those ages 25–29 the rate fell from 80 to 58. In contrast, the first birth rate for college graduates ages 30–34 rose from 19 to 36 during these years and for women ages 35–39, the rate increased from 5 to 9 per 1,000 women (Table 2).

Greater educational attainment is associated with more timely receipt of prenatal care and a better outcome in terms of birthweight. For example, of first births to college graduates ages 30–34, only 5.8 percent were low birthweight (less than 2,500 grams or 5 pounds 8 ounces) compared with 7.5 percent of all first births to mothers in this age group.[1] In addition to seeking prenatal care very early in pregnancy, well-educated women are much more likely to be well-nourished and to gain

adequate weight during pregnancy as well as to curtail behaviors such as smoking which could affect pregnancy outcome.[7–9]

In recent years the number of babies born in the United States has been increasing because the number of women in the childbearing ages has risen. Birth rates by age of mother, however, have risen only for relatively older women.[10] The fact that a growing fraction of women giving birth for the first time are 30 years old or older may have implications for health care providers. For example, cesarean deliveries are more likely for older mothers.[11] Older mothers are at greater risk for certain complications,* and their babies are at higher risk of being of low birthweight and of having certain congenital anomalies.[10,12] Additionally, the much greater labor force participation rate of these older mothers may have implications in terms of child care needs. About two-thirds of first-time mothers ages 30–44 were in the labor force in June 1986 compared with half of women having their first child at ages under 25 years.[6] The data in this report can provide a basis for decisions on these medical, health, and child care issues.

Errata

An error in the printing of Appendix Table 2 was recently found in the article by Sempos, *et al*, in the November 1988 Journal.[1] For 1979, the sum of the age-adjusted mortality rates of Ischemic Heart Disease and Hypertensive Heart Disease for black females should be 129.1. Also for 1979, the sum of the age-adjusted mortality rates of Ischemic Heart Disease, Hypertensive Heart Disease, and Cardiovascular Disease Unspecified for white males, white females, black males, and black females should be 244.9, 111.2, 254.2, and 151.0, respectively.

Also, the SOURCE should read: "Prepared by authors using data from the NCHS, Division of Vital Statistics." The editorial staff of the Journal regrets this error.

REFERENCE

1. Sempos C, Cooper R, Kovar MG, McMillen M: Divergence of the recent trends in coronary mortality for the four major race-sex groups in the United States. Am J Public Health 1988; 78(11):1422–1427.

* * *

In the paper by Lurie, *et al*,[1] May 1989 issue of this Journal, there is an error in the Table 2.

In column three, headed "Diff. (95% CI)," under the main heading of "Free", the % with natural impairment having an eye examination should read (3, 13) rather than (3, 3) as appeared in the published version. The authors regret that this error was not caught in the galleys.

REFERENCE

25th Anniversary

XXV INTERNATIONAL GRADUATE SUMMER SESSION IN EPIDEMIOLOGY

Presented by the University of Michigan
School of Public Health
(Formerly held at the University of Minnesota)
July 8 - 28, 1990

Three Week Courses:
- Introduction to Epidemiology for Health Practioners
- Epidemiology I- Fundamentals of Epidemiology
- Epidemiology II-Design and Conduct of Epidemiologic Studies
- Epidemiology III-Advanced Statistical Methods in the Analysis of Epidemiologic Studies (July 16-27)
- Fundamentals of Biostatistics
- Microcomputer Applications in Epidemiologic Research
- Epidemiology, Control and Prevention: Infectious Diseases
- Epidemiology, Control and Prevention: Chronic Diseases
- Epidemiology and Health Policy
- Epidemiology of Injuries

One Week Courses:
- Basic Concepts of Clinical Epidemiology
- Clinical Trials- Design and Conduct
- Clinical Trials- Analytic Methods
- Sexually Transmitted Diseases
- AIDS
- Drug Abuse
- Environmental Exposure Assessment
- Occupational Epidemiology
- Pharmacoepidemiology

For application and information contact:
Dr. David Schottenfeld, Professor and Chairman, Department of Epidemiology or
Jody Gray, Administrative Coordinator
Graduate Summer Session in Epidemiology
The University of Michigan
School of Public Health
109 Observatory Street
Ann Arbor, MI 48109-2029

Effect of Disinfectants on Pseudomonads Colonized on the Interior Surface of PVC Pipes

Roger L. Anderson, PhD, Betty W. Holland, Janice K. Carr, BS, Walter W. Bond, MS, and Martin S. Favero, PhD

Abstract: We investigated the effect of disinfectants on microbial contamination present on the interior surface of polyvinyl chloride (PVC) pipes filled with 600 ml of water contaminated with *Pseudomonas pickettii* and *P. aeruginosa*. After eight weeks, water was removed, and the test pipes exposed to various types of aqueous disinfectants. Disinfectant samples were removed, neutralized, and examined for recovery of microorganisms by membrane filtration. After seven-days exposure, disinfectant solutions were removed and pipes filled with sterile distilled water. Water was examined by membrane filtration at seven-day intervals to determine whether the organisms had survived in the pipes. Colonization of PVC surfaces were examined during each study phase by scanning electron-microscopy (SEM). *P. aeruginosa* was isolated directly from iodophor disinfectant, phenolic germicide, and iodophor antiseptic solutions. After addition of sterile water, *P. aeruginosa* was recovered from PVC pipes previously exposed to chlorine, phenolic, quaternary-ammonium, and iodophor disinfectants; *P. pickettii* was recovered from water in pipes treated with iodophor disinfectant, chlorine, and ethanol. The existence of glycocalyx-like cellular masses on the interior wall of PVC pipes most likely protected embedded organisms from the microbicidal action of some of the disinfectants tested and served as the reservoir for continuous contamination. (*Am J Public Health* 1990; 80:17–21.)

Introduction

The resistance of microorganisms to antimicrobial agents in general and chemical germicides in particular is controlled by a number of factors including the culture history and strain of the microorganism, the nature of the suspending menstruum as well as a variety of physical factors such as temperature, pH, and hardness. Further, microorganisms in their naturally occurring state have been shown to be significantly more resistant to chemical germicides than microorganisms that have been subcultured on artificial culture media.[1,2]

In the last several years, however, there have been reports of bacteria surviving in concentrations of chemical germicides that go significantly beyond the perceived limits of resistance. For example, recent epidemiologic and microbiologic investigations have documented intrinsic microbial contamination of iodophor antiseptic solutions.[3–6] Pseudobacteremia caused by *Pseudomonas cepacia* has been associated with the use of contaminated povidone-iodine, and *Pseudomonas aeruginosa* peritoneal infections has been attributed to the use of contaminated poloxamer-iodine. Presently, epidemiologic and laboratory investigations involving a contaminated povidone-iodine solution are in progress. Peritoneal infections in infants and false positive blood cultures from intensive-care unit patients with *P. cepacia* have been associated with the use of this intrinsically contaminated povidone-iodine antiseptic solution.[7] In addition, the prolonged survival of *P. aeruginosa* in iodophor solutions has been demonstrated after the iodophor was exposed to the inside surfaces of naturally contaminated PVC water distribution pipes.[8,9] When these organisms were isolated from iodine solutions and then tested, high numbers ($>10^6$ per ml) of *P. aeruginosa* were inactivated by iodophor solutions in minutes. More recently, studies have been completed which show recovery of *P. aeruginosa* from iodophors after unused or new PVC, stainless steel, copper, and glass pipes were artificially contaminated with water containing these organisms and subsequently exposed to iodine antiseptic solutions.[8]

The isolation and extended survival of microorganisms in these iodine-containing solutions may be due to extracellular glycocalyx-like material that microorganisms form and deposit on a variety of different types of surfaces.[10–12] Microbial colonization on the interior surfaces of PVC pipes and subsequent protection of organisms from the microbicidal action of antiseptic solutions may be due to the formation and adherence of extracellular matrixes to PVC surfaces. The end result is the production of thick masses of cells and extracellular material (biofilms). Once these masses are formed, antibacterial agents such as disinfectants or antiseptics must saturate the matrix before they can kill bacteria within adhesive biofilms.

Because PVC pipes are commonly used to distribute water in many pharmaceutical and manufacturing plants, in hospital dialysis units, and in various laboratory facilities, we initiated laboratory studies to determine: 1) the effects of various chemical germicidal disinfectants on *Pseudomonas* spp. colonizing the interior wall surfaces of new PVC pipe; 2) the observation and importance of thick cellular masses on PVC surfaces by SEM; and 3) if bacteria survive in and recolonize test pipes after exposure to chemical disinfectants. The purpose of these studies was to formulate a model system to determine the reason for the extraordinary ability of *P. cepacia* and *P. aeruginosa* to survive for extended periods of time after exposure to chemical germicides.

Methods

Preparation of PVC Test Pipes and Sample Remnants

Schedule 80 PVC pipe (4.1 cm in diameter) was used in these investigations. Test pipes consisted of two 30.4 cm PVC sections attached to a 90° PVC elbow. Straight pieces of PVC were separately attached to the elbow by pipe putty (Rectorseal, The Rectorseal Corp, Houston, TX), teflon tape (Teflon Thread Seal, DuPont, Wilmington, DE), organic solvents (Oatey PVC Cement, Oatey Co, Cleveland, OH), or dresser couplings (Flo-Control, Burbank, CA). Thus, four

Editor's Note: See also related editorial p 13 this issue.

sections of PVC (distinguished by the type of attachment) were included in each test group. All PVC test pipes were thoroughly rinsed with tap water, dried, and separately packaged before ethylene oxide sterilization; rubber stoppers used to plug the pipe ends were steam sterilized.

Remnant samples for SEM were prepared by cutting small (1.5 by 1.5 cm) squares of PVC pipe. A small hole was bored at one end and a single 30.5 cm piece of monofilament fishing line tied to each PVC square. Remnant samples were packaged and sterilized with ethylene oxide before suspending them in PVC test pipes.

Microbiologic Conditioning of Test PVC Pipes and Remnant Samples

PVC test pipes (two test groups evaluated each week for four weeks) were filled with 600 ml of water containing a mixed, naturally occurring bacterial population which included only *P. aeruginosa* and *P. pickettii*. These organisms were originally present in naturally contaminated manufacturing plant water and served as the inocula for maintaining a source of contaminated water for these investigations. A reservoir of contaminated water was maintained by inoculating an 18-liter plastic carboy of sterile deionized water with 500 ml of contaminated plant water. Water in the carboy was held at ambient temperature (25°C), and contained a total microbial level of 10^4 colony-forming units (CFU) per ml at the beginning of this study. Initially, contaminated water present in the PVC test pipes contained 10^2 *P. aeruginosa* and 10^2 *P. pickettii* per ml of water.

Five remnant samples were suspended in rubber-plugged pipes filled with contaminated water. Pipes were then stored for eight weeks at 25°C to effect microbial colonization of the interior PVC surfaces. Microbial populations in the pipe waters were sampled weekly using membrane filtration procedures as described. Ten-fold water dilutions were made and passed through sterile sampling tubes attached to bacteriological membrane field monitors (0.45 micron; Millipore Corp, Bedford, MA). PVC remnants were removed at various time intervals for SEM observation of microbial colonization (i.e., formation of cellular and extracellular material accumulations).

Scanning Electron Microscopic Examination of PVC Remnants

For SEM studies, the PVC remnants were fixed in 1 percent glutaraldehyde in Sorenson's PO_4 buffer (pH 4.9) for 16 hours at room temperature, then rinsed three times in PO_4 buffer (pH 7.0). Postfixation was in osmium tetroxide (1 percent in PO_4 buffer, pH 7.0) for four hours at room temperature. The remnants were dehydrated in a graded ethanol series and then placed in a critical-point drying apparatus. Critical-point drying was carried out with CO_2 as the transitional fluid-drying gas. Specimens were loaded into the unit while immersed in 100 percent ethanol, and drying was accomplished by successive changes of liquid Co_2 while the apparatus was chilled by an ice/water bath. The CO_2 was removed by the temperature and pressure being raised to the critical point (32°C and 1100 psi) and slowly exhausted. Specimens were sputter-coated with gold palladium and examined in a Philips SEM 515.

Disinfection of Contaminated PVC Test Pipes

After eight weeks of incubation, contaminated water in the PVC test pipes was removed and cultured quantitatively using ten-fold dilutions and membrane filtration procedures as previously described. Two disinfectants were evaluated each week in two groups of PVC test pipes. Four contaminated PVC test sections (representing the four types of pipe attachment), or one PVC test group, were totally filled (*ca.* 600 ml) with each of the following disinfectants: 1) a 1:213 aqueous dilution (pH 2.9) of an iodophor detergent-germicide (Wescodyne, West Chemical Co, Lynbrook, NY); 2) a 1:128 aqueous dilution (pH 9.2) of a phenolic germicidal detergent (Vesphene II, Vestal Laboratories, St. Louis, MO); 3) a 1:256 aqueous dilution (pH 8.9) of a quaternary-ammonium germicidal detergent (Hi-Tor, Huntington Laboratories Inc, Huntington, IN); 4) a stock solution (pH 5.0) of an iodophor antiseptic (Prepodyne, West-Agro Chemical Co, Inc, Westwood, KS, manufactured for AMSCO Medical Products Division, Erie, PA); 5) 2 percent glutaraldehyde (Cidex, Surgikos, Inc, Arlington, TX) of pH 8.0; 6) a aqueous dilution (pH 7.5) of purified-grade sodium hypochlorite (Fisher Scientific Co, Fair Lawn, NJ) having 10–50 mg of free available chlorine per liter, as determined by the DPD colorimetric test method (Hack Company, Loveland, CO); 7) a 2 percent aqueous dilution (pH 3.4) of formaldehyde (Whiteworth Inc, Gardena, CA); and 8) 70 percent (vol/vol) aqueous ethyl alcohol (Warner-Graham Co, Cockeysville, MD) of pH 5.4. Two control PVC pipes were evaluated with each disinfectant test group: one noncontaminated PVC pipe with disinfectant and one water-contaminated PVC pipe with sterile distilled water.

Aliquots (10 to 50 ml) of the disinfectant were removed and sampled using membrane filtration procedures at 0, 2, 4, and 6 hours and 1, 2, 3, 5, and 7 days. After sampling, each pipe was refilled with an equal amount of the appropriate disinfectant. Filters were rinsed with 250 ml of brain heart infusion broth with 0.5 percent beef extract and the appropriate neutralizer. The filters were placed on blood agar plates. The following chemicals (i.e., in final percent concentration) were added to the enriched broth to neutralize any residual disinfectant: 0.5 percent sodium thiosulfate for iodophors and chlorine solutions; 0.5 percent Tween 80 for phenolics; 0.7 percent lecithin (soybean) for quaternary ammonium compounds; and 0.25 percent sodium bisulfite for aldehydes. Blood agar plates with filters were incubated for 24–48 hours at 35–37°C. The microbial count was recorded per aliquot sampled and subsequently expressed as CFU per ml. To insure that *P. aeruginosa* and *P. pickettii* were the only organisms in the mixed microbial population that was used to condition the PVC pipes, two representative colonies of each morphologic type were picked from the filters and inoculated to triple sugar iron agar slants. Organisms showing nonfermentative reactions on these slants were identified by standard biochemical tests.[13]

Recolonization of PVC Pipes Previously Exposed to Disinfectants

After the contaminated pipes were exposed to disinfectants for seven days, the pipes were emptied and each was refilled with 600 ml of sterile distilled water. Pipes were resealed with fresh sterile rubber stoppers. Water was removed at seven-day intervals and various ten-fold dilutions were examined by membrane filtration procedures as previously described to determine reestablishment of microbial contamination in PVC test pipes previously exposed to chemical disinfectants. After dilutions were filtered, the membrane filters were placed directly on blood agar plates (no neutralizer rinse) and incubated.

Results

Microbiologic Conditioning of PVC Test Pipes

Over the eight-week conditioning period, water counts

for *P. pickettii* (biovar Va-1) were higher (10^5 to 10^6 CFU per ml) than counts observed for *P. aeruginosa* (10^3 to 10^5 CFU per ml). The microbial count for each organism increased each week during the eight-week sampling time. Total viable counts were approximately ten-fold higher in PVC test pipes that used pipe putty (a pipe-threading compound) to attach individual straight pieces to the 90° PVC elbow than pipes that did not have putty.

SEM Examination of PVC Remnants Exposed to Contaminated Water

The presence of bacterial colonization (i.e., formation of cells embedded in extracellular material) on the interior surface of PVC sample remnants was observed by SEM after remnant exposure to contaminated water (Figure 1). Microorganisms were not observed on control PVC remnants (samples not exposed or conditioned with contaminated water).

Recovery of Organisms from Test Disinfectants

P. aeruginosa was recovered directly from an iodophor disinfectant and a phenolic germicidal detergent in 48 hours and from an iodophor antiseptic solution in five days (Table 1). *P. pickettii* was not isolated from any of the test chemicals through seven days of sampling. *P. aeruginosa* and *P. pickettii* organisms were recovered from each of the 32 sterile water controls (i.e., four controls for each test disinfectant). The method of attaching PVC sections to the 90° PVC elbow did not correlate with recovery of organisms from test disinfectants.

Reestablishment of Organisms in Sterile Water

P. aeruginosa was recovered from water placed in PVC pipes previously exposed for seven days to use dilutions (i.e., diluted product as recommended by the manufacturer) of either an iodophor disinfectant, a phenolic germicidal detergent, a quaternary-ammonium compound, an iodophor antiseptic, or a dilution of sodium hypochlorite; *P. pickettii* was recovered from the pipes treated with an iodophor disinfectant, a chlorine solution, or 70 percent ethanol (Table 2). There was no evidence of microbial contamination during 42 days of sampling from contaminated PVC pipes exposed to 2 percent glutaraldehyde or 2 percent formaldehyde and refilled with sterile water. In some instances, organisms were found in water present in the PVC test pipes but were not recovered from the corresponding disinfectant initially used to disinfect that group of pipes.

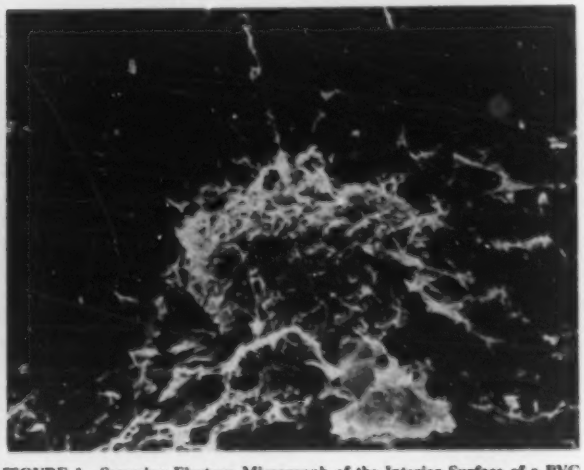

FIGURE 1—Scanning Electron Micrograph of the Interior Surface of a PVC Remnant Sample after Eight Weeks of Exposure to Contaminated Water. × 3,800

Discussion

Previous investigations have demonstrated the prolonged survival of *P. aeruginosa* in naturally contaminated PVC water distribution pipe segments after they were exposed to iodophor antiseptic solutions.[8,9] In one study, *P. aeruginosa* was isolated from a poloxamer-iodine solution 48 hours after membrane-filter sterilized poloxamer-iodine was added to the interior surface of naturally-contaminated PVC water pipe. Continuous exposure of poloxamer-iodine to this pipe resulted in a level of 10^4 CFU per ml of *P. aeruginosa* at nine days. This contaminated solution of poloxamer-iodine was removed from the pipe, stored at 25°C, and served as the reservoir for prolonged microbial survival studies. Using this contaminated stock solution of poloxamer-iodine, we found that *P. aeruginosa* (10^4 CFU per ml) survived for as long as 98 days in stock solution after removal from the PVC pipe.[8] Based on this investigational approach, a suitable laboratory model for induction of survival of these organisms and for studying the mechanism of *Pseudomonas* resistance to iodophors was developed.

In addition, studies have been done in which unused pipes of different composition were artificially contaminated by exposure to contaminated water containing *P. aeruginosa*.[8] After seven days, the water was removed from each pipe, and all were filled with membrane-filtered poloxamer-iodine. *P. aeruginosa* was recovered from poloxamer-iodine after exposure to artificially-contaminated PVC, stainless steel, copper, and glass pipes, but not galvanized steel pipe.

Thus, the newly developed model of using both naturally and artificially contaminated PVC pipes proved useful in demonstrating iodophor-resistance of *P. aeruginosa*. To date, the addition of iodophor antiseptic solutions to contaminated PVC pipe is the only laboratory method now available to show recovery and survival of *P. aeruginosa* from iodophor antiseptics.

We report experiments designed to determine: 1) the effect of various germicides on *Pseudomonas* spp. colonizing PVC pipe; 2) the existence of glycocalyx-like structures as a potential survival mechanism for these organisms; and 3) the reestablishment of *Pseudomonas* spp. in sterile distilled water added to contaminated and disinfectant-treated PVC pipes. *P. aeruginosa* was recovered from three test germicides during a seven-day exposure period: an iodophor disinfectant and phenolic germicide in 48 hours and an iodophor antiseptic in five days. *P. aeruginosa* was not recovered from either a quaternary-ammonium germicidal detergent, 2 percent glutaraldehyde, 10–50 ppm chlorine, 2 percent formaldehyde, or 70 percent ethyl alcohol; *P. pickettii* was not isolated from any of the eight disinfectants tested. The variable microbicidal capabilities of the germicides tested could be due to the type and amount of bacterial colonization present in the PVC pipes, the presence of morphologically abnormal bacterial cytoplasm in cells, or the specific mode and site of action of test disinfectants on bacterial cells (such as microorganisms embedded in a matrix of extracellular material).

Recent review articles have discussed contaminated antiseptics and disinfectants and the various types of orga-

nisms associated with these contaminated chemical solutions[14] as well as the resistance of bacteria to antiseptics and disinfectants.[15] A more definitive answer as to why *Pseudomonas* may survive or even grow in germicidal solutions will most likely not be available until laboratory studies are completed which clarify the mechanism of germicidal activity and determine the biologic and ecologic characteristics of *Pseudomonas* spp. that permit their tolerance to or utilization of various chemical compounds.

Massive concentrations of bacterial cells were observed by SEM on the surface of PVC remnant samples after incubation in contaminated water. These cellular masses (or glycocalyx-like structures) appeared to develop in greater numbers as the length of exposure time to contaminated water increased. As suggested in this investigation, the existence of glycocalyx-like structures and the shedding of these structures from interior PVC wall surfaces most likely served to shield *P. aeruginosa* from the microbicidal action of iodophor and phenolic germicides (Table 1).

The protective effect of the bacterial glycocalyx has been suggested by several investigators.[8–12,16] But it should be noted that our preparative techniques for SEM observations were not sufficient to preserve the entire glycocalyx matrix as described by Coseterton, *et al.*[10] Although we observed a considerable degree of microbial adhesion accompanied by notable accumulations of extracellular material on the PVC surfaces, our visual observations are likely an underestimation of the actual amount of physical mass. The prolonged survival of *Serratia marcescens* in 2 percent chlorhexidine was most likely due to these microorganisms being embedded in a thick matrix which adhered to the walls of storage jugs containing this antiseptic solution.[17] Viable *S. marcescens* was recovered from 2 percent chlorhexidine during a storage period of 27 months. The recovery of *P. aeruginosa* from unopened bottles of poloxamer-iodine could be the result of contaminated water and PVC product distribution pipes from a manufacturing plant.[16] SEM micrographs of these pipes demonstrated large concentrations of rod-shaped and coccobacillary cells embedded in interior deposits of the pipe. Also, large numbers of *P. aeruginosa* (10^4 CFU per ml) survived for as long as 98 days in a stock solution of poloxamer-iodine after exposure and removal from naturally contaminated PVC water distribution pipe.[8]

In the present study, microorganisms were observed to survive and reestablish in sterile water placed in PVC pipes previously exposed to chemical germicides. Although *Pseudomonas* spp. were not recovered from some of the test disinfectants, they were isolated from water that was placed in the corresponding chemically-treated test pipes. This reestablishment of microbial contamination suggests a continuous reservoir of organisms adhering to and shedding from the interior PVC wall surface. Organisms showing survival in five PVC test pipes were *P. aeruginosa* (after exposure to chlorine or a quaternary ammonium compound) and *P. pickettii* (after exposure to a iodophor disinfectant, chlorine, or 70 percent ethanol). This is strong evidence that these organisms survived within the colonized PVC pipes after exposure for seven days to a variety of chemical treatments. The physical thickness of cellular and extracellular material that form on PVC pipe surfaces could protect organisms from the action of germicidal chemicals and serve as a continuous reservoir for microbial contamination in test pipes and of water flowing through pipes.

Other investigators have hypothesized the importance of cell masses such as the glycocalyx as a potential reservoir of microbial contamination.[18,19] Several recent investigations have implicated *P. aeruginosa* as the etiologic agent of whirlpool-associated infections (i.e., folliculitis). These organisms are capable of growing in water and colonizing various whirlpool surfaces including water pipes. Such cellular and extracellular material accumulations adhering to whirlpool surfaces could protect bacteria from the action of chlorine and provide a constant microbial reservoir resulting in the contamination of water after a chemical treatment.

The public health significance of this investigation and its findings are widespread. PVC pipes are commonly used in

laboratory facilities, pharmaceutical and manufacturing plants, hospitals, therapeutic and public whirlpool-type hot tubs, and homes to distribute water for various usages. In 1984, during an investigation of a manufacturing plant which produced iodophor antiseptics, *P. aeruginosa* contamination was recovered throughout the PVC water distribution system.[16] Subsequently it was found that intrinsic contamination of a poloxamer-iodine antiseptic solution resulted when the formulated iodophor was allowed to stand in contaminated PVC pipes (pipes between the mixing tank and storage tank and between the storage tank and the bottling area) prior to bottling. As remedial measures, the company removed all PVC pipes, installed new stainless pipe, and initiated a hot water sanitizing procedure (60°C water for one hour) of all process water and product distribution pipes. In addition, better and more frequent microbiological quality control procedures on municipal and process water were instituted.

These types of laboratory studies are important in identifying possible mechanisms by which microorganisms could survive in disinfectant solutions for extended periods of time and to determine how bacterial organisms could continuously contaminate the various parts within a water distribution system. The best way to maintain a water distribution system in a safe condition is to limit the number of microorganisms by proper and scheduled maintenance and to routinely sanitize pipes or tubing that transport water. The laboratory findings presented here add to development of effective strategies for disinfecting water or product distribution lines and holding tanks in manufacturing plants and in laboratory, medical, and pharmaceutical facilities where microbial contamination by pseudomonads or other naturally-occurring gram-negative water bacteria is a problem.

Public Health Workforce Consortium Recommended

Development of a Public Health Workforce Consortium with public and private representatives—to study health personnel implications of strategic public health issues and improve data collection efforts—has been recommended by a work group established by the Health Resources and Services Administration (HRSA).

The HRSA-supported group recommended the study of selected issues such as those delineated by the Year 2000 Health Objectives for the Nation. It also recommended an incremental approach to the eventual creation of an analytical system capable of assessing the public health work force.

Information on the Public Health Workforce Consortium project and its recommendations is available from B. Jerald McClendon, Division of Associated and Dental Health Professions, Bureau of Health Professions, Room 8C-09, DHHS/PHS, 5600 Fishers Lane, Rockville, MD 20857. Telephone: (301) 443-6757.

First Nursing Home Admissions: Time Spent at Home and in Institutions after Discharge

MARY ANN LEWIS, RN, DRPH, BARBARA LEAKE, PHD, MARGARET LEAL-SOTELO, MSW, AND VIRGINIA CLARK, PHD

Abstract: We tracked 96 percent of a sample of 1,942 nursing home patients admitted to a nursing home for the first time in 1982–83. Patients discharged alive from the nursing home were followed for two years or until death. The relative time spent at home, in hospitals, and in skilled nursing facilities is reported.

Of the 705 patients discharged from their initial nursing home admission to homes in the community, about 50 percent made only one transfer and only 15 percent made four or more transfers. Of the 509 discharged to a hospital, 26 percent died there and 37 percent of the 374 survivors made four or more moves in the next two years. In all, 1,332 patients were discharged alive and they spent almost two-thirds of the subsequent two years, or their remaining lifetimes, in the community. Of those who transferred only once, over two-thirds of their follow-up time was spent in their own homes. Policies concerned with long-term care should use some type of actuarial data base to successfully plan and implement long-term care insurance. (*Am J Public Health* 1990; 80:22–24.)

Introduction

As the United States population continues to age, there is growing concern over the costs of long-term care and the importance of developing mechanisms to finance such care.[1,2] Projections of the costs of an insurance program should be based on data that includes patients' use of all types of services and facilities in the health care system, their survival, and the resources required to provide services to maintain them at home. Despite the size of the long-term care segment of the health care system, and the need for its services, relatively little is known about patients' continued use of services, especially non-institutional services, until death.[3]

Our previous longitudinal studies of defined nursing home populations examined the immediate discharge outcomes of nursing home care in three cohorts of elderly patients (1980, 1982–83, 1984).[4–6] Over time there were no changes in casemix or immediate discharge outcomes of persons admitted to nursing homes for the first time (first admissions).[5] However, a comparison of first admissions and readmissions showed that readmissions were sicker and had worse short-term outcomes.[6] A comparison of readmissions in 1980 and 1984 showed 1984 readmissions were more debilitated than those in 1980 and less likely to return home.[7] Further, readmissions who had been admitted from hospitals in 1984 were almost twice as likely to be rehospitalized within 30 days compared to all readmissions in 1980.

Using a small cohort of patients in 1980, we did a preliminary examination of the number of post-discharge transfers for two years after the initial discharge from the nursing home.[8] In the present study, we provide a detailed report on the continued use of services including time spent at "home" and in institutions, over a two-year period using a 1982–83 discharge cohort of first admissions to nursing homes.

Methods

A cohort of 1,942 patients discharged in 1982–83 from 45 non-hospital based skilled nursing facilities (SNFs) in the urban areas of San Bernardino/Riverside/Ontario in Southern California comprised the total sample. A detailed account of the data collection methods for this first nursing home admission sample has been reported.[5]

The initial discharge outcomes were classified as:

- returned to home in the community,
- transferred to another nursing home,
- died in the nursing home,
- transferred to the hospital and died there, and
- transferred to the hospital and survived (i.e., subsequently discharged alive from the hospital to a nursing home or to a home in the community).

Patients discharged alive were followed for a period of two years or until death following their initial discharge from a nursing home. The location and associated follow-up information for patients discharged alive were obtained from hospital and nursing home medical records, correspondence with medical record librarians, and telephone interviews with family and friends. This patient relocation information was obtained for two years after the initial nursing home discharge by recording each patient's change of setting: length of stay in that setting, and whether the patient was discharged alive or dead from that setting. Time at home in the community was separated into days spent in the patient's "own home," which included their personal home or that of a relative or friend, days in a retirement home, and days spent in a board and care facility.

Length of life was calculated from the time of discharge from the initial nursing home until death or the end of the two-year follow-up period. Deaths were verified in the county vital statistics records.

This paper describes the associations between number of transfers (0, 1, 2, 3, and 4, or more) and patients' immediate discharge outcomes. It also provides detailed documentation on patients' length of stay in the initial SNF, all subsequent SNFs, hospitals, and homes, including their own (or that of friends or relatives), as well as retirement and board and care homes, according to the number of transfers. Because distributions of survival are skewed, both medians and means are reported.

Results

We successfully tracked 96 percent (N = 1865) of the

total sample of patients (N = 1,942) for the two-year follow-up. Those patients lost to follow-up (N = 77) were excluded from the analysis. At two years, a review of county death records showed that none of the 77 patients lost to follow-up had died in the study area.

Table 1 shows the association between the initial nursing home discharge outcome and the number of subsequent transfers (0–4 or more) for two years. Over one-fourth (N = 533) of the total patients tracked (N = 1,865) died in the nursing home. Almost 30 percent (N = 550) made only one transfer; of these, 11 percent moved to other SNFs, and 64 percent returned to homes in the community. The remainder (25 percent) went to hospitals where they died.

About 18 percent (N = 342) of all patients made two transfers after discharge from the SNF. Of these, 50 percent were discharged to hospitals and survived; 44 percent initially returned to homes in the community; the rest moved to another SNF. Ten percent (N = 187) of all patients made three transfers; of these 16 percent initially went to other SNFs; 35 percent were discharged to hospitals and lived; and almost half returned to homes in the community. The remainder of the patients (N = 253 or about 14 percent) made four or more transfers; only 3 percent of this group were discharged to other SNFs; 55 percent went to hospitals and survived; and 42 percent returned initially to homes in the community.

Put another way, of the 705 patients discharged from their initial nursing home admission to homes in the community, 354 (about 50 percent) made only one transfer and only 15 percent (106/705) made four or more transfers. Of the 509 discharged to a hospital, 26 percent died there; and of the 374 survivors, 37 percent made four or more moves in the next two years.

Table 2 summarizes the survival time of each group making at least one transfer, the proportion alive at two years, and the relative distribution of days of life spent in various locations, i.e., SNFs, hospitals and homes in the community after discharge from the initial nursing home.* An overall summary is also given for all patients discharged alive. The median survival time after discharge for the entire cohort of patients was 157 days. After eliminating those individuals who died in the nursing home, the median survival time was 617 days. Patients discharged alive from the nursing home spent 65 percent of their remaining time during the two-year follow-up in the community. Following discharge from the nursing home, these individuals spent approximately 33 percent of their time in SNFs, 3 percent in hospitals, 11 percent in board/care homes, 3 percent in retirement homes, and 51 percent in their "own" homes.

The median survival in days was 293 for those who transferred twice,and 691 days for those who made three transfers.[9] Because of censored data related to missing information on long-term survivors, we were unable to compute the median survival for individuals who made one and four or more transfers.

As indicated in Table 2, only those making either two or four or more transfers spent the majority of their lives during the two-year follow-up period in institutions. Of those making only one transfer, 53 percent were alive at two years, and as a group they spent over 86 percent of their follow-up days in the community, with over 67 percent of those community days being spent in their "own" homes. For those making three transfers, over half of their post SNF discharge days of life during follow-up were also spent in the community, and the vast majority of that time in the community was spent in the patients' "own" homes. Of the 1,332 patients in Table 2 who spent variable proportions of their remaining days of life at home, 56 percent were disoriented, 46 percent were incontinent of stool and/or urine and 76 percent were dependent in activities of daily living.

*Note that "any home" in the Table includes board/care, retirement and "own" homes.

TABLE 2—Distribution of Time Spent in Various Locations after SNF Discharge and Survival for Two Years According to Number of Transfers

	Number of Transfers				
	1	2	3	≥4	All
No. of Patients	550	342	187	253	1,332
Median LOS in Initial SNF	33	28	36	29	32
% Alive at Two Years:	53	33	49	53	47.2
Median Survival in Days:*	—	293	691	—	617
(Average)**	444	360	483	538	448
% Days Spent In:					
SNF	13.0	49.5	38.1	50.1	32.6
Hospital	0.5	3.1	4.6	5.5	2.7
Board/Care	15.0	7.2	7.6	7.0	10.4
Retirement Home	4.0	2.5	3.0	1.0	2.9
Own Home	67.5	37.7	46.7	36.4	51.4
Any Home***	86.5	47.4	57.3	44.4	64.7

*—Unable to compute median due to censored data related to long-term survivors.
**Censored data causes average survival to be biased because information is lacking on long-term survivors.
***"Any Home" includes all types of homes, i.e., board and care, retirement patient's own home, and the home of a friend or relative.

TABLE 1—Association between Initial Nursing Home Discharge Outcome and Number of Post Discharge Transfers for Two Years

				Transferred from SNF to:			
					Hospitals		
Number of Transfers	Number of Patients	Percentage of Patients	Died in SNF	SNF	Died	Lived	Home*
0	533	28.6	533	0	0	0	0
1	550	29.5	0	61	135	0	354

3	187	10.0	0	29	0	65	93
≥4	253	13.6	0	9	0	138	106
Totals	1,865	100%	533	118	135	374	705

*Home includes all types of homes, i.e., board and care, retirement, patient's own home, and the home of a friend or relative.

Discussion

This study documents the subsequent number of transfers and resource utilization of a discharge cohort of 1,865 patients admitted to skilled nursing facilities for the first time. Almost 30 percent of the sample died in the nursing home, but among those who survived, an unexpected and interesting finding was the length of time many of these patients spent in homes (usually their "own") in the community after being discharged.

The transfer of the frail elderly with variable needs for continued care from one setting to another is a function of several factors. Clearly health status or requirements for care affect placement, especially for those with the greatest need for 24-hour care. The supply of beds, reimbursement policies and patients' economic resources interact to limit length of stay in different facilities. Finally, the preferences of patients and families may well be the determinant of placement at home or in a long-term care facility for those with the personal and or economic resources to exercise this option. This study clearly demonstrates the magnitude of "at home" care utilized by those who survive their first nursing home admission. There are no reported studies, to date, of the relative importance of the variables listed above in determining the mobility of this population, and the non-institutional costs of providing care for them.

Thirty percent of these patients made just one transfer after discharge, and then spent over two-thirds of the succeeding two years, or their remaining lifetime in their own home or that of a friend or relative. There is no reported information related to the family and community resources required for this amount of home care. Over one-half of the individuals making one transfer survived the two-year follow-up period. This represents a considerable amount of time at home. Given the burden of care requirements these patients present, one can only speculate about the degree to which their nursing care requirements were met, the impact of their need for care on family resources, and how (already mentioned this in terms of degree) the challenge was partitioned among family, friends, and other home care providers. Clearly, the need for a more detailed study of patients' continuing care needs (and how these were met) is apparent. Whether or not the families of these individuals managed independently to care for their loved ones or used community nursing agencies is important information for those concerned with policy. Another economically relevant issue that deserves consideration is lost work time for family caregivers.

Information on the specific care requirements for the significant portion of the persons in the sample who were living at home two years after discharge is particularly essential. Such data (while not collected in this study) can best be derived from longitudinal tracking of patients, a research design not commonly used in nursing home studies.[10]

As indicated in previous publications, the area for this study represents the 37 standard statistical metropolitan (SMSA) areas throughout the country with the exception that it has a lower proportion of Blacks and individuals below the poverty level. It may or may not represent the population in the eight urban SMSAs, e.g., New York City, Los Angeles, San Francisco, etc.

This data set does provide a fairly detailed picture of the natural history of continuing care for a modest sample of patients for two years after discharge from nursing homes. Estimates of costs may be derived from the number of days spent in various institutional settings (hospitals, skilled nursing facilities, board and care homes). Advocates of long-term care insurance will require some type of actuarial data base of individual patients' utilization of facilities and resources to successfully plan and implement long-term care insurance. However, what is conspicuously missing from this report is information on the services provided to these individuals and their social and economic costs during those intervals spent at home. More information of this type is essential to planning for the care of the rapidly growing numbers of frail elderly, and assisting families to cope with the burdens of their care.

ACKNOWLEDGMENTS

We thank the patients, their families and friends, for providing information related to the migration patterns. We also thank Dr. Robert L. Kane for his assistance in the development of this study, and the nursing homes and hospitals for their cooperation in helping us to complete the study. Support for this study was provided by the National Center for Health Services Research, Grant Number HS04946. Computer support was provided by the UCLA School of Nursing.

Cocaine and the Risk of Low Birth Weight

Diana B. Petitti, MD, MPH, and Charlotte Coleman, BA

Abstract: In a population-based case-control study, we assessed the relation between cocaine use and the risk of low birth weight in Alameda County, California, excluding women who used heroin and/or methadone during pregnancy. After adjustment for confounders, the relative risk of low birth weight in users of cocaine throughout pregnancy was 4.0 (95% CI = 1.8, 8.9). Cocaine use was estimated to account for 10 percent of cases of low birth weight in Black women in Alameda County. (*Am J Public Health* 1990; 80:25–28.)

Introduction

Cocaine use affects pregnancy outcome adversely in animals.[1,2] In humans, it has been associated with an increased risk of abruptio placenta[3,4] and of intrauterine growth retardation and pre-term delivery.[5–11] In a population-based case-control study of low birth weight in Alameda County, California, we estimated the relative risk of low birth weight in relation to use of cocaine and the contribution of cocaine use to the problem of low birth weight in this urban population.

Methods

Subjects were identified using information from Alameda County, California birth certificates. Eligible were singleton infants without congenital anomalies whose mother and father were both Black or both White, non-Hispanic, born in Alameda County between January 1, 1987 and December 31, 1987 to residents of Alameda County. Cases weighed 500 through 2499 grams. Controls were chosen at random from among infants with weights of 3000 or more grams, the number of controls in each ethnic group being equal to the number of cases.

We identified 500 Black cases and 500 Black controls and 268 White, non-Hispanic cases and 268 White, non-Hispanic controls for the study, but nine records were subsequently judged ineligible. After obtaining permission from the California Vital Statistics Advisory Committee to use information from the confidential section of the birth certificate and the approval of our study protocol and interview instrument by two local committees for protection of human subjects, we used information on the birth certificate to locate women, who were given a detailed explanation of the study's aims, of the risks and benefits of participation, along with assurances of the confidential nature of the information provided. Consenting women were interviewed in their homes by trained interviewers. Ultimately, 766 of 994 eligible Black mothers (77.1 percent) and 462 of 533 eligible White mothers (86.7 percent) were interviewed.

Women were separately queried about use of cocaine and of "crack" or freebase cocaine, which is the smoking of pure crystalline cocaine.[12] Information about other potential confounders was also collected by interview.

Cases of low birth weight were sub-classified into three groups: ≤1500 grams (very low birth weight), 1501–2500 grams and <37 menstrual weeks of gestation (low birth weight, pre-term), and 1501–2500 grams and ≥37 menstrual weeks of gestation (low birth weight, term, intrauterine growth retarded) according to suggestion of Yerushalmy.[13]

The relative risk of low birth weight was estimated using the exposure odds ratio. The chi-square statistic was used for polychotomous variable. Ninety-five percent confidence intervals were estimated using the method of Cornfield,[14] except when these failed to converge, in which case the method of Kleinbaum and Kupper was used.[15] Logistic regression as implemented on SAS[16] was used to estimate relative risk controlling for confounders.

The population attributable risk percent was estimated using methods described by Walter.[17] The population prevalence of cocaine use in Whites and Blacks was estimated as the sum of the number of cases who used cocaine and the number of controls who used cocaine multiplied by the relevant sampling ratio (26.32 for Whites and 7.75 for Blacks) divided by the estimated total number of White or Black deliveries in Alameda County.

Results

Seven Black women and four White women who used heroin and/or methadone during pregnancy, and four Black women with incomplete information on cocaine use, were excluded from all analyses. After these exclusions, both the use of cocaine in forms other than crack throughout pregnancy and the use of crack throughout pregnancy were associated with large increases in the risk of low birth weight (Table 1).

No White women admitted to use of crack or cocaine in other forms throughout pregnancy, and multivariate analysis was confined to Blacks. Because of the small number of controls who admitted to use of cocaine or crack throughout pregnancy, we combined the categories for cocaine and crack use throughout pregnancy. After adjustment for confounders, the increased relative risk of low birth weight in women who used cocaine and/or crack throughout pregnancy persisted but was attenuated (Table 2).

Low pre-pregnancy weight and low weight gain may be caused at least in part by use of cocaine, and a history of having a prior low birth weight infant may be related to use of cocaine in the prior pregnancy. Thus, a multivariate statistical model that includes these factors may "over

From the Alameda County Low Birth Weight Study Group.* Address reprint requests to Diana B. control" by adjusting for these factors. In multivariate analyses that excluded these variables and adjusted for confounders, the relative risk of having a low birthweight infant in women who used cocaine and/or crack throughout pregnancy was still elevated by a factor of about 4 to 5 (Table 2).

The use of cocaine and/or crack throughout pregnancy increased the relative risk of very low birth weight, pre-term low birth weight, and intrauterine growth retardation in Blacks by about the same amount (Table 3).

Based on an estimate that the prevalence of use of cocaine and/or crack throughout pregnancy is 3.9 percent among Black women in Alameda County and an estimate that the relative risk of low birth weight in users of cocaine and/or crack throughout pregnancy is 4.0 after adjustment for confounding, the attributable risk of low birth weight for cocaine and/or crack use throughout pregnancy in Black women in Alameda County can be estimated to be 0.10.*

Discussion

This study joins a growing body of research[3–11] that links maternal cocaine use with poor pregnancy outcome. The study is unique in being population-based. Results show that cocaine use increases the risk of both pre-term delivery and intrauterine growth retardation, a finding that also is in keeping with the findings of most other similar studies,[5–11] that of Chasnoff, *et al*,[4] being an exception.

This study has some important limitations:

- We did not interview all of the women eligible for the study, although consideration of the characteristics of the non-interviewed women, who mostly could not be located, suggest they would be *more* likely than those we interviewed to use cocaine.
- Information on cocaine use was based on self-report. It is unlikely that women would overreport use of an illegal drug, thus spuriously increasing the risk of low birth weight in association with cocaine use, but we cannot exclude this possibility entirely.
- Mothers of cases of low birth weight might have selectively overreported cocaine use because of concern or guilt about an adverse outcome, or for other reasons. The number of mothers of cases who selectively overreported cocaine use would have to be very large to explain our findings.
- Women may have reported cocaine use but not use of drugs, such as heroin, that are known to reduce birth weight. It is not easy to understand why women would report cocaine use and not use of other illegal drugs, but this explanation for our results cannot be excluded.
- Our study is limited in its ability to draw conclusions about dose-response, because our definition of cocaine use is imprecise. We do not have information about the amount of cocaine use or the timing of its use during pregnancy, because we did not ask these questions.

Considering these limitations and in the context of a large body of data linking cocaine use with intrauterine growth retardation and pre-term delivery,[3–11] we conclude that cocaine use is an important contributor to the public health problem of low birth weight in the Black population of Alameda County, and probably in other urban settings where there is substantial use of the drug. Women who cease cocaine use in the first trimester of pregnancy have been shown to have no increase in the risk of pre-term delivery or growth retardation.[9] Even though specific programs to reduce cocaine use during pregnancy have not been evaluated, the evidence linking cocaine use with poor pregnancy outcome appears sufficient to warrant interventions that provide counseling and a broad-based community effort to identify women early who use cocaine in their pregnancies. The magnitude of the increase in the risk of poor pregnancy outcome in cocaine users suggests that the success of efforts to improve infant and perinatal mortality in settings where use is common may be dependent on addressing the problem of cocaine use successfully.

U-MI Offers Non-Residential Graduate Programs in Health Administration and Policy

Two programs at the University of Michigan School of Public Health, Ann Arbor, offer mid-career professionals the opportunity to earn non-residential graduate degrees while continuing to hold down full time jobs:

- The University's *On Job/On Campus Program in Health Services Administration*—a non-residential masters degree (MHSA or MPH) program—is now accepting applications for its Fall 1990 class. Classes are held in Ann Arbor over a four-day weekend, once per month, for a two-year period.

This program is designed to offer mid-career professionals in the fields of management, policy analysis, medicine, dentistry, nursing, etc., advanced training in health care management and policy through a broad conceptual and analytical approach to the medical care system, with intensive course work in management skill areas such as financial management, economics, statistics, and operations research. The On Job/On Campus Program in Health Services Administration, begun in 1972, now has over 200 graduates working in all aspects of the health care system.

- The University's Department of Health Services Management and Policy offers the *Pew Doctoral Program in Health Policy*, a non-residential program for experienced health care professionals. The Pew Program, which allows students to remain employed full time while pursuing the DrPH degree, is designed for persons with prior graduate education who wish to prepare for positions of substantial influence in health policy.

Pew doctoral students complete their course work by meeting each month in Ann Arbor for one long weekend, Thursday through Sunday, for two years. During the third year of the program, they meet for three weekend sessions as part of a series of activities and services designed to encourage and facilitate work on their dissertation. Applications are now being accepted for the Fall 1990 term; Pew scholarships are available to students in the program.

For additional information and application forms on either program, contact: David Perlman, MPH, OJ/OC/Pew Program Manager, School of Public Health, University of Michigan, M3525 SPH II, Ann Arbor, MI 48109-2029. Telephone: (313) 936-1191.

Cigarette Smoking as a Risk Factor for Sudden Infant Death Syndrome: A Population-Based Study

BENGT HAGLUND, DRMEDSC, AND SVEN CNATTINGIUS, MD

Abstract: Risk factors for sudden infant death syndrome (SIDS) were examined in a prospective study based on Swedish births between 1983 and 1985. All infants surviving the first week of life were included (279,938). The overall rate of SIDS was 0.7 per 1,000 first week survivors. Elevated relative risks were associated with low maternal age, multiparity, maternal smoking, and male infants. Smoking doubled the risk and a clear dose-response relation by amount smoked was observed. Maternal smoking also seemed to influence the time of death, as infants of smokers died at an earlier age. In countries like Sweden, smoking may be the single most important preventable risk factor for sudden infant death syndrome. (*Am J Public Health* 1990; 80:29–32.)

Introduction

Although syndromes similar to sudden infant death syndrome (SIDS) have been known since biblical time, progress in solving the enigma of SIDS has been slow. The incidence of SIDS varies widely, being low in Scandinavia[1] and higher in other industrialized countries, e.g., in North America. In Sweden[2] and Finland,[3] the incidence of SIDS has doubled since the 1970s, despite reductions in the infant mortality rate of almost 40 percent.[2]

SIDS and other causes of infant death share some risk factors, but the age at death distinguishes SIDS from the other causes of death.[4] SIDS victims usually die within one to six months of age; for unknown reasons, there are two peaks of age at death: eight to nine weeks, and 13 to 15 weeks.[2,5]

Low social class and maternal smoking have previously been associated with SIDS.[1,3,4] Since smoking is more frequent in lower social classes,[6] it is uncertain whether the increased risk for SIDS should be ascribed primarily to smoking or low social class.

In 1973, a medical birth registry was set up by the National Board of Health and Welfare in Sweden,[7] and, since 1982, information has been collected prospectively for each pregnancy from the first antenatal visit. The registry provided an excellent opportunity to investigate the influence of maternal smoking and other risk factors on SIDS in an unselected, homogeneous low-risk population.

Methods

The Swedish National Board of Health and Welfare receives demographic data, previous reproductive history and pregnancy outcome on all hospital births. This is transmitted as copies of the standardized antenatal and obstetrical records, which are generally used in Sweden. In the first trimester, midwives at the antenatal care clinics record previous reproductive history, smoking habits, and family situation. Practically all Swedish women visit these clinics regularly during pregnancy.[8] All births reported to the birth registry are validated every year against a population registry at Statistics Sweden, which receives information from the parishes about all births and deaths. This cross-checking is done by using the mother's personal identification number. The Medical Birth Registry covers more than 99 percent of all births in Sweden.[9]

During the study period from 1983 to 1985, 280,256 infants survived the first week of life. The study was restricted to births of mothers between 15 and 44 years of age. The 318 births for which maternal age was either unknown or outside this interval were excluded, leaving a total of 279,938 infants for study. Ninety-five percent of these infants were born to Scandinavian women.

In Sweden, the death certificate includes information about when the death occurred, possible causes of death, and whether or not an autopsy was performed. In the present investigation, 698 infants were reported to have died between one and 51 weeks of age. SIDS was reported as the only cause of death in 190 infants (International Classification of Diseases, ICD 8, 1968, 795,99). Autopsies were performed on 98 percent of the cases (94 percent forensic and 4 percent clinical). Most deaths from other causes also had autopsies (58 percent clinical and 12 percent forensic).

Parity was defined as the number of live births plus stillbirths. Smoking habits were categorized as non-smoker (i.e., non-daily smoker), moderate smoker (smoking between one and nine cigarettes per day), or heavy smoker (10 cigarettes or more per day). Since it is common in Sweden for young couples to live together without being married, information about family situation was recorded as whether or not living with infant's father.

Multiple logistic regression analyses were performed in order to calculate associations of the independent variables on SIDS as estimated by the relative risk.[10] The independent variables used in the analyses were maternal age, parity, family situation, smoking habits, type of birth (single or multiple), and sex of infant. The continuous variables were categorized in order to avoid assumptions about linearity. The statistical analyses were made using the SAS program package.[11,12]

Results

Mortality from SIDS, 190 cases or 0.7 per 1,000 first week survivors during the three years, accounted for about 27 percent of the total infant mortality after the first week of life. Table 1 shows that maternal age was inversely associated with risk for SIDS. Other characteristics of the mothers associated with an excess number of SIDS were high parity, not cohabiting with infant's father and the number of cigarettes smoked per day. Higher risks for boys and for multiple births were also seen.

TABLE 1—Number of Infants Surviving the first Week of Life and SIDS Death Rate by Characteristics of the Mother and Infant, Sweden, 1983–85

Characteristics	Infants No.	SIDS No.	SIDS Death-rate per 1000
Maternal Age at Delivery (years)			
15–19	9,574	14	1.46
20–24	66,582	53	0.80
25–29	103,527	68	0.66
30–34	68,838	41	0.60
35–39	27,155	12	0.44
40–44	4,262	2	0.47
Parity			
1	112,994	52	0.46
2	101,323	75	0.74
3	47,333	38	0.80
≥4	18,288	25	1.37
Family Situation			
Living with father	253,588	164	0.65
Not living with father	14,436	17	1.18
Not available	11,914	9	0.76
Smoking Habits			
Non-smoker	181,218	88	0.49
Daily smoker			
1–9 cigarettes	48,465	45	0.93
≥10 cigarettes	31,225	46	1.47
Not available	19,030	11	0.58
Sex of Infant			
Boy	143,981	110	0.76
Girl	135,391	79	0.58
Not available	566	1	...
Type of Birth			
Single	274,526	184	0.67
Multiple	5,407	6	1.11
Not available	5	0	...
Total	279,938	190	0.68

Smoking habits varied with age and family situation: half of the teenage mothers smoked compared with 25 to 29 percent of mothers aged 25 or more. More than half of women who were not living with infant's father were daily smokers, compared to 29 percent of those living with infant's father.[13] We therefore adjusted the estimates for the effects of other variables using a multiple logistic regression model (Table 2).

As seen in Table 2, high parity strongly increased the risk for SIDS, but high maternal age reduced the risk of SIDS. It is plausible that the effect of parity varies with age, but we detected no interaction between age and parity ($p = 0.6$). Infants not living with their father had 50 percent greater SIDS mortality than those living with their father (95% CI = 0.8, 2.5).

Maternal smoking was strongly related to SIDS even when controlling for other risk factors. Smoking up to nine cigarettes per day doubled the risk of SIDS and smoking 10 cigarettes or more per day nearly tripled the risk of SIDS, compared to non-smokers. We examined whether smoking increased the risk of SIDS mortality more for certain women than others, but no clear interactions were detected (smallest p-value = 0.11).

Age at Death of SIDS Infants

The age at death from SIDS ranged widely with a peak incidence at nine to 12 weeks. The age distribution reported from other studies—two peaks during the first six months of life[2,5]—was not clearly observable in our study. Only when the age of death was grouped by three-week intervals was there a weak tendency toward an early and a late peak.

The SIDS victims were stratified into two groups of equal size. However, before this was done, the 10 percent with the longest survival time were excluded in order to obtain groups including only cases with typical ages at death. Early SIDS were defined as deaths occurring between seven and 67 days of age and late SIDS were those between 68 and 145 days of age. Although the magnitude of the risks differed between the two models, they were in general rather similar (Table 2). However, moderate maternal smoking almost tripled the risk for early SIDS, while no increase in the risk for late SIDS appeared. A similar but less marked pattern was true for infants not living with their father.

For further analyses of the difference between early and late SIDS, a logistic regression model based only on the SIDS cases was performed, to estimate the probability of dying before 68 days of age among the SIDS victims. The analysis showed that moderate maternal smoking was strongly associated with increased risk for early SIDS (RR 1.7, 95% CI = 1.2, 2.1). SIDS victims whose mothers were heavy smokers (RR 1.4, 95% CI = 0.9, 1.4), or not living with infants father (RR 1.8, 95% CI = 0.9, 2.3), also had an increased risk for short survival, while infants of mothers 35 years of older seemed to have higher probability for longer survival (RR 0.4, 95% CI = 0.1, 1.1).

The influence of maternal smoking on the time of dying from SIDS, is illustrated in Figure 1. Infants of non-smoking mothers had a symmetric age distribution with a mode value of nine to 12 weeks. Infants of smoking mothers however, had a right-skewed age distribution with a shorter modal time of survival, five to eight weeks.

Discussion

In the present study, the diagnosis of SIDS was based on cases where the death certificate stated SIDS as the only cause of death. As 98 percent of these cases underwent autopsy (and 94 percent forensic autopsy), the diagnostic accuracy in these cases must be considered as sufficient. The diagnostic difficulties of SIDS, when using death certificates, mainly concern underregistration,[2] so the incidence estimated (0.7 per 1000) may be an underestimate.

Maternal smoking has earlier been reported as a risk factor for SIDS.[5,14,15] In the present study, a strong association between maternal smoking and SIDS was found. We have no direct measures of confounders associated with smoking that might adversely affect the infant. For instance, we have no information on whether there were other smokers in the household. However, adjustment for the effects of maternal age, parity, and family situation only marginally reduced the estimates. Such socio-demographic variables are also related to behavioral and lifestyle characteristics that could adversely affect the infant. It therefore seems unlikely that unmeasured confounders would appreciably influence the association. The present results were based on a prospective study, including about 280,000 infants. The population studied was a relatively homogeneous, low-risk population, which further suggests a limited influence of possible confounders.

The information on smoking habits was based on the mothers' reports to the midwives at their first visit to antenatal care. As practically all women in Sweden regularly visit these clinics during pregnancy, the influence of possible selection bias seems negligible.[8] Since pregnant women today are exposed to anti-smoking information, this may have influenced the validity of self-reported smoking habits.

TABLE 2—Relative Risks* of Sudden Infant Death Syndrome Based on a Logistic Regression Model (257,361 Infants Surviving the first Week of Life in Sweden 1983–85)

	All SIDS (1–51 weeks) Relative risk (95% CI)	Early SIDS (7–67 days) Relative risk (95% CI)	Late SIDS (68–145 days) Relative risk (95% CI)
Maternal Age (years)			
15–19	2.0 (1.0, 4.0)	1.5 (0.5, 4.4)	2.6 (0.9, 7.6)
20–29 (ref. group)	1.0	1.0	1.0
30–34	0.7 (0.5, 1.0)	0.6 (0.3, 1.0)	0.8 (0.5, 1.5)
35–44	0.5 (0.2, 0.8)	0.3 (0.1, 0.8)	0.8 (0.4, 1.7)
Parity			
1 (ref. group)	1.0	1.0	1.0
2–3	2.2 (1.5, 3.3)	2.8 (1.6, 4.8)	2.2 (1.2, 3.9)

Multiple	1.5 (0.7, 3.4)	2.1 (0.8, 5.8)	1.1 (0.3, 4.5)

*Estimates are adjusted for all other variables.

Moreover, women may also have stopped smoking during pregnancy. It has been reported elsewhere that 15 to 20 percent of pregnant smokers quit "on their own" during pregnancy.[16,17] Thus, if a causal relationship between maternal smoking and SIDS exists, the true relative risk may be even greater than estimated herein.

Other studies have reported low birthweight to be associated with SIDS[3,18] and smoking to be associated with low birthweight.[17] Because the effect of maternal smoking on SIDS could be mediated by low birthweight, we also conducted an alternative analysis controlling for low birthweight (<2500 grams). We found almost the same risk estimates for smoking (RR = 1.7 and RR = 2.5 for moderate and heavy smoking, respectively) indicating that smoking affects birthweight-specific as well as overall SIDS mortality.

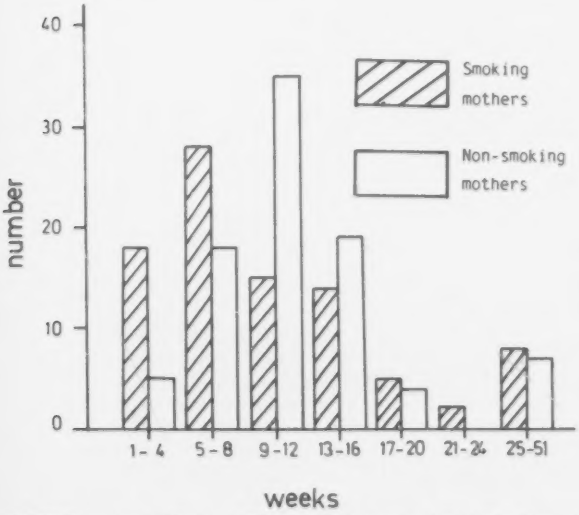

FIGURE 1—Age in Weeks of SIDS Infants in Sweden 1983–85 by Maternal Smoking Habits

The socioeconomic factor included in this study (cohabiting vs not cohabiting parents) has previously been associated with SIDS in Scandinavia,[2,19] but information about maternal smoking was not included in those studies. In the present study, the crude relative risk of SIDS was 1.9 in non-cohabiting families, but daily smoking was more common among non-cohabiting women. Adjusted for the effects of differences in smoking habits, the relative risk was reduced to 1.5 (95% CI = 0.8, 2.5). These data suggest that smoking is a confounding factor, through which at least some of the effects of social class on SIDS rate are mediated, at least in the homogeneous populations of Sweden, where poverty and malnutrition are practically non-existent.

The previously reported bimodal age distribution of SIDS[2,5] led us to stratify the SIDS cases into early and late SIDS. The most striking difference in risk factor pattern between early and late SIDS was the influence of maternal smoking, a finding in accordance with Golding, *et al.*[5] Early SIDS was more strongly related to maternal smoking. We suggest that the reported bimodal age distribution may partly reflect differences in maternal smoking.

Today, smoking is probably the most important preventable risk factor for late fetal death.[13,20] The present results suggest that this may also hold true for SIDS. Assuming that maternal smoking could be eliminated and infants delivered by mothers who gave up smoking faced the same mortality risk as their non-smoking peers (i.e., same maternal age, parity, sex, etc.), we estimated that SIDS death rate would be reduced by 27 percent. In terms of number of SIDS deaths, this means a reduction from 190 deaths to approximately 140 deaths during a three-year period in Sweden.

ACKNOWLEDGMENTS

We are very indebted to Anders Ericsson, Director, and Jan Gunnarskog, Programmer, at the National Board of Health and Welfare, for providing data for this investigation.

An earlier version of this study was presented orally in Swedish at the annual meeting of the Swedish Medical Association in December 1988.

The 1990 National Conference on
Community Responsive Practice: Values, Priorities & Strategies
March 21-22, 1990
The Hyatt Regency, Crystal City, Virginia

Sponsored by:
The American Medical Student Association/Foundation
The National Association of Community Health Centers
The National Rural Health Association
The U.S. Public Health Service

The Conference will occur during the first one and one half days of AMSA's 40th Anniversary Celebration. The program will emphasize the need in this country for community health as a vital, integrated discipline. It will celebrate what has already been accomplished in the field and will provide a forum for strategizing on what needs to be done in order for community health to be recognized as a credible and essential cornerstone of this nation's health-care system. AMSA would like to extend a special invitation to its alumni to join in the conference and to help celebrate the organization's 40th anniversity.

Past Pregnancy Outcomes among Women Living in the Vicinity of a Lead Smelter in Kosovo, Yugoslavia

Mary J. Murphy, MD, MPH, Joseph H. Graziano, PhD, Dusan Popovac, MD, PhD, Jennie K. Kline, PhD, Ali Mehmeti, MD, Pam Factor-Litvak, MS, Gemail Ahmedi, MD, Patrick Shrout, PhD, Biljana Rajovic, MD, Dragoslav U. Nenezic, MD, and Zena A. Stein, MB

Abstract: This analysis compares the rates of spontaneous abortion among women living in the vicinity of a lead smelter with those of women living in a town where blood lead levels were low. Data derive from the obstetric histories of both groups of women obtained while seeking prenatal care for a later pregnancy. A total of 639 women (304 exposed, 335 unexposed) had at least one previous pregnancy and lived at the same address since their first pregnancy. The geometric mean blood lead concentrations in the sample at the time of the interviews were 0.77 μmol/L in the exposed town and 0.25 μmol/L in the unexposed town.

The rates of spontaneous abortions in first pregnancies were similar, with 16.4 percent of women in the exposed town and 14.0 percent in the unexposed town reporting loss. The adjusted odds ratio relating town of residence to spontaneous abortion was 1.1 (95% CI = 0.9, 1.4). This analysis represents the first systematic attempt to seek an association between environmental lead exposure and spontaneous abortion. As such, the failure to find a positive association strongly suggests that at the levels of exposure represented in our sample, such an association does not exist. (*Am J Public Health* 1990; 80:33–35.)

Introduction

Historical anecdotes have suggested that occupational exposure to lead may be detrimental to reproductive outcome. Pregnant women working in the pottery and white lead industries in England in the nineteenth century were reported to be more likely to miscarry than women not so employed; other reports from Italy, Germany, France, and Japan also describe high rates of loss among pregnant women exposed to lead as compared to women without exposure.[1] While most samples lack both precise measures of exposure and information on potentially confounding factors, taken together they suggest that high levels of lead might be harmful to the developing conceptus. This suggestion is consistent with a series of reports from Sweden, where Nordstrom and co-workers found a significantly increased frequency of spontaneous abortion among female employees working at a lead smelter.[2] Similar observations were made on populations living in close proximity to that smelter.[3]

In contrast, a recent prospective cohort study of pregnant women living near a lead smelter in Australia reported no association between maternal blood lead (BPb) and spontaneous abortion.[4] That study, however, may have suffered from incomplete ascertainment of the event.[5] The present report examines the rates of spontaneous abortion in two comparable populations, one living in the vicinity of a lead smelter and the other in a town 25 miles away without significant environmental lead exposure.

Methods

The subjects of this analysis were recruited for a prospective cohort study of environmental lead exposure, reproductive outcome, and infant development. Further description of the population and methods of data collection have been presented in a recent publication.[6] The past reproductive histories of these women provide the data for this report. In brief, the study took place in Titova Mitrovica (T. Mitrovica), Yugoslavia, where there is significant environmental exposure to lead from a lead smelter, refinery, and battery plant, and in Pristina, Yugoslavia, a town without significant lead exposure. The prospective cohort study recruited women in mid-pregnancy. At that time an interview inquiring about medical and reproductive history and sociodemographic factors was administered.

A total of 1,502 women was recruited at mid-pregnancy. This analysis draws on data from the first 1,032 recruited during the period of May 1985–May 1986. Of the 1,032 women evaluated, 777 (332 in T. Mitrovica and 445 in Pristina) had had at least one previous pregnancy. In T. Mitrovica, the current BPb varies with distance from the smelter, such that women living close to the smelter have, on average, higher blood lead (BPb) levels than those living further away.[6] Since it is reasonable to assume that this variation in BPbs with distance from the smelter was also true in the past, it is only among women who have not moved since their first pregnancy that we can be assured of previous lead exposure during that pregnancy. Accordingly, this analysis was confined to 639 women (304 in T. Mitrovica and 335 in Pristina) who had lived at their current address at least since their first pregnancy.

In these analyses, spontaneous abortion was defined as a fetal loss prior to the seventh month of gestation; stillbirth was defined as a fetal loss occurring in months seven through nine of gestation. Only the first pregnancy of each woman was used in the analysis. This strategy avoids the problem of nonindependence of reproductive outcomes within individuals.[7,8] Maximum likelihood logistic regression analysis was used to assess the influence of lead on spontaneous abortion, after adjustment for the effects of potentially confounding variables.[9]

Results

Table 1 shows the demographic characteristics of the 639 women with at least one previous pregnancy who lived in the same home since their first pregnancy. Mean parental ages at

TABLE 1—Demographic Characteristics at Study Recruitment

Characteristics	T. Mitrovica	Pristina
Number of women	304	335
Mean maternal age at first pregnancy	21.7 (3.9)*	22.1 (3.4)
Mean paternal age at first pregnancy	26.0 (4.8)	25.6 (4.0)
Mean maternal education (years)	8.7 (4.0)	8.7 (3.9)
Mean paternal education (years)	11.3 (2.7)	11.2 (3.0)
Mean number of previous pregnancies	2.8 (2.2)	2.6 (2.0)
% Current cigarette smokers	23.0	26.3
% Current alcohol users	5.9	10.5
% Same address since birth	31.0	30.2
Mean years at current address	13.6 (10.1)	7.0 (6.4)
% Husbands employed in Pb industry	28.8	—
Ethnicity		
% Albanian	59.3	63.3
% Serbian	21.5	25.6
% Other	19.2	11.1

*Standard deviation.

first pregnancy, mean parental years of school at the later index pregnancy, and gravidity were similar in the two towns. Women in Pristina compared to women in T. Mitrovica were slightly more likely to be current smokers and twice as likely to be current alcohol users. While approximately 30 percent of women had lived in their respective towns since birth, women in T. Mitrovica had lived an average of six years longer at their current address than women in Pristina. Within this sample, the proportions of women of Albanian and Serbian origin were higher in Pristina.

Hematologic findings at the time of study recruitment revealed the expected differences in BPb and erythrocyte protoporphyrin (EP) (Table 2). Mean BPb in T. Mitrovica was 0.77 μmol/L as compared to 0.25 μmol/L in Pristina. The mean hemoglobin concentrations were within normal limits in both towns.

The rates of spontaneous abortions were similar in T. Mitrovica (16.4 percent) and Pristina (14.0 percent) (Table 3). Stillbirth rates were also similar across towns. When all fetal losses were combined, the rate in T. Mitrovica was 19.7 percent; the rate in Pristina was 17.9 percent. These rates remained essentially unchanged when adjusted for the number of induced abortions in each town.[10]

Adjustment for the effects of maternal age at first pregnancy, current smoking, ethnic group, and maternal education by maximum likelihood logistic regression produced little change in the odds ratio relating town of residence and spontaneous abortion (odds ratio 1.1) (Table 3). Refinement of the exposure variable using distance of the home from the smelter showed no consistent trend in the odds ratio using Pristina as the reference group. For women living within 2 km of the smelter, the adjusted odds ratio was 1.2 (95% confidence interval = 0.7, 1.9); for those within 2–4 km it was 2.1 (0.8, 5.3); for those within 4–8 km it was 0.5 (0.2, 1.2); and for those beyond 8 km it was 0.8 (0.6, 1.6). Analysis of the data restricted to women who reported never drinking alcohol showed similar results.

TABLE 2—Current Blood Lead and Hematology Findings

	T. Mitrovica	Pristina

TABLE 3—First Pregnancy Outcome Rates

	T. Mitrovica	Pristina	Odds Ratio[c]
	% (number)	% (number)	(95% CI)
Spontaneous Abortions[a]	16.4 (50)	14.0 (47)	1.1 (0.9, 1.4)
Stillbirths[b]	3.9 (10)	4.5 (13)	1.0 (0.6, 1.5)
Livebirths	80.3 (244)	82.1 (275)	—

[a]Denominator excludes reported induced abortions, ectopic pregnancies, and pregnancies where the outcome was unknown.
[b]Denominator excludes spontaneous abortions.
[c]Adjusted for maternal age, current smoking, ethnic group, and maternal education.

Discussion

These data indicate that lead exposure, at the levels encountered in T. Mitrovica, is not a risk factor for spontaneous abortion. The adjusted odds ratio was 1.1 with an upper bound of 1.4 suggesting larger effects are unlikely. There was 80 percent power to detect an odds ratio of 1.6 (alpha = 0.05, two tailed).

In order to increase our confidence that this result is real and not due to bias, we examined carefully the basis for measuring exposure, outcome, and confounding variables. Town of current residence is the index of exposure in this analysis and the population of women examined lived at least since their first pregnancy in the same home. While current blood lead is a marker of recent exposure, the striking differences in current blood leads between these two groups, together with the fact that these women had not moved since their first pregnancies, make it likely that exposure at first pregnancy similarly differed across towns. Moreover, previous blood and air lead survey data from these two towns indicate that the levels of exposure in T. Mitrovica were probably higher in the past.[11] Thus, previous levels of lead exposure such as might have occurred in the first pregnancies of these study women are likely to have been higher than those recorded at present. We remain assured that the index of exposure is an appropriate one, that the exposure differs across towns, and that the levels of exposure in T. Mitrovica among currently pregnant women are significantly higher than those in Pristina. We note, however, that the level of lead exposure of our subjects in T. Mitrovica does not nearly approach that typically found among women exposed to lead through occupation.

In reviewing this study, one could speculate about the possible effects of random or differential misclassification of spontaneous abortion. Insofar as spontaneous abortion rates are similar to those reported in other samples, the stillbirth rates comparable to those found in less developed countries, there is no basis for positing high levels of misclassification. Differential misclassification might be produced if recall differed between towns. In order to produce the null result observed here, we must posit bias in opposite directions for the two towns: underreporting in T. Mitrovica and overreporting in Pristina. Again, since the rates of loss in both towns fall well within the bounds usually reported, such biasing effects seem unlikely.

Previous work which examined the relation of lead exposure to spontaneous abortion revealed inconsistent find-

ings. The initial historic reports which suggested an association are largely based on anecdotal reports of women working in lead-related industries where more severe and multiple occupational exposures may have been operating. These observations gave rise to the hypothesis of a causal relation, but did not provide systematic evidence of such an association. The Swedish smelter studies,[2,3] although suggestive of an effect of environmental exposure on spontaneous abortion, were largely ecologic and thus do not provide strong support for an association at the individual level.

The only prospective cohort study to address the issue of lead and reproductive outcome assessed 831 pregnant women living near a lead smelter in Australia.[4] In that study, mean blood lead levels (std error) among the exposed were relatively low, ranging from 0.51 ± 0.01 to 0.54 ± 0.01 μmol/L. Blood lead and other risk factors were examined in relation to pregnancy outcome and no association was found between maternal BPb and spontaneous abortion. However, the number of abortions ascertained was small (n = 23) raising the question of incomplete ascertainment of the event.[5] The failure to find a positive association in the current study strongly suggests that, at the levels of exposure represented in our sample, such an association does not exist.

Call for Proposals: Improving Service Systems for the Physically Disabled

The largest single commitment of private funds ever provided to benefit people with disabilities has been announced by the Robert Wood Johnson Foundation of Princeton, NJ. The Foundation will award up to $8.4 million to community-based organizations run by and for the disabled. As many as 12 one-year planning grants of up to $100,000 will be made under the Foundation's new program, "Improving Service Systems for People with Disabilities."

The grant funds are intended to help community organizations such as Independent Living Centers create comprehensive service systems so that the disabled can live independently. Community organizations that receive the planning grants also will be eligible to compete for three-year grants of up to $600,000 to carry out their plans to coordinate available health and supportive services, develop new services, and identify public and private financing sources for these services.

The application deadline is January 16, 1990. Organizations intending to apply should contact Lex Frieden, Independent Living Research Utilization, 3400 Bissonnet, Suite 101, Houston, Texas, 77005 or call 713/528-0504. The grants awards will be announced in the fall of 1990.

The Effect of a Patient Education Program on Emergency Room Use for Inner-City Children with Asthma

MARK C. SHIELDS, MD, MBA, KENNETH W. GRIFFIN, BA, AND WYLIE L. MCNABB, EDD

Abstract: An educational program for children with asthma designed to reduce emergency room (ER) use enrolled all eligible children (n = 253 primarily low-income Black) within a health maintenance organization (HMO) who had used the hospital or ER for asthma during the pre-enrollment period and randomized them into two groups. Twenty-four of the experimental group patients had 55 ER visits and 18 of the control patients had 39 ER visits during the first 12 months post-intervention. This program did not achieve its goal. (*Am J Public Health* 1990; 80:36–38.)

Introduction

Asthma is a common disease that leads to considerable morbidity and expense.[1] Lethal asthma is a serious problem and continues to increase in frequency, especially for minority patients.[2] The years of potential life lost due to asthma almost doubled for minority males between 1979 and 1983.[3] One of the strategies to reduce morbidity, mortality, and expense of asthma has been patient education. The program evaluated in this paper was designed to improve patients' knowledge and behaviors related to asthma in order to improve their control of the disease, and thereby reduce emergency room (ER) use.

Methods

Subjects

Subjects were drawn from two facilities of an urban health maintenance organization (HMO) with a combined enrollment of over 50,000. Approximately 80 percent of these patients were Black and all had at least one working adult in the family. The median household income for the HMO service area was 6 percent below the overall city median. Patients were eligible for inclusion in the study if they were 18 years of age or younger and had at least one emergency room visit or hospitalization for asthma during the prior four-year period. A total of 253 subjects met eligibility requirements. All eligible patients were enrolled in the study.

Randomization

For randomization purposes, patients were listed in order of their past emergency room use and descending this list patients were allocated randomly using a table of random numbers to either experimental (n = 127) or control (n = 126) groups. The random assignment was balanced so that out of every 10 assignments, five were to the experimental group. The experimental and control groups were virtually identical on several measures as shown in Table 1.

Data Collection

The HMO collected information on hospital days, emergency room visits, and office visits including the related diagnoses during its normal course of business. Once a patient dropped out of the HMO, no further information was available. The enrollment and dropout of patients were monitored by the HMO. Utilization outside the HMO while a member was recorded because virtually all other emergency rooms and hospitals would have billed the HMO for their services.

TABLE 1—Profile of total Group [N = 253]

	Experimental Group	Control Group
Number of Patients	127	126
Mean Age (years)	8.5	9.0
Sex (% male)	61%	65%
ER Use before entry (# visits in 1 year)	1.2	1.2
Months in HMO before entry	20.5	21.2
Percent registered at largest HMO center	48.0	49.2
Percent with one or more hospital days for asthma in prior year†	18.2	23.6

†Percent shown for patients for whom data are available.

Educational Program

The program consisted of two components: classes conducted in group settings for patients and their parents, and telephone instruction by protocol to patients or parents by nurse clinicians to provide additional instruction and reinforcement. The classes and calls covered 23 instructional objectives grouped into four content areas: 1) prevention of asthma attacks, 2) medication management, 3) intervention during asthma attacks, and 4) utilization of health care resources. Instruction dealt with knowledge, skills, and behavior. Four classes were offered to each patient and his or her parents on weekday evenings and Saturday mornings with make-up sessions scheduled periodically to accommodate patients who missed classes. Each class lasted 1.5 hours. Following classes, telephone instruction by protocol to patients and their parents was done at least each season. The calls typically lasted 30 minutes.

The program was offered to all 127 experimental group patients. Of the patients who remained in the HMO for 12 or more months, 38 percent attended one or more classes. Telephone instruction by protocol improved patient contact to 81 percent. The mean number of educational contacts (classes plus calls) was 4.4. The intervention increased the frequency of self-reported mastery on most of the instructional objectives. The post-intervention mastery of specific educational objectives varied from 80 percent of patients for avoidance of over-the-counter drugs, 75 percent of patients for quitting smoking, 35 percent of patients for recognition of

© 1990 American Journal of Public Health 0090-0036/9051.50

the early signs of an asthma attack, to 30 percent of patients for using medicines correctly. Detailed descriptions of the program content, instructional techniques, and educational outcomes for these patients have been reported previously.[4,5]

Exposure of control group patients to the intervention was unlikely because the program was performed apart from the primary care providers and the program staff avoided routine contact with those providers. The control group continued to receive their usual medical care.

Results

Of the 253 patients who began the program, 205 remained within the HMO for the first 12 months and 194 remained within the HMO for the entire study period, up to 29 months. Dropouts were evenly distributed between experimental and control groups. Participants and dropouts were compared according to age, sex, and ER use before entry. The differences were small and not statistically significant.

There was no significant difference between experimental and control groups in post-intervention health care utilization for respiratory related illnesses for a one-year period as shown in Table 2. This analysis excludes dropouts and eliminates any seasonal bias, since each patient was enrolled for 12 continuous months. Hospital days and office visits also are compared. Further analysis (not shown in this table) revealed no differences in utilization for non-respiratory illnesses. The results were similar when this analysis was repeated for the total time period of the study with all dropouts included. The probability of a Type II error for a clinically significant difference was calculated and found to be negligible.

Discussion and Conclusions

The program did not achieve its goal of decreasing emergency room visits for children with asthma. This occurred despite careful program design, implementation by clinicians with expertise in pulmonary disease, and an average of $96 expended per patient per year (1984 dollars) for the asthma education.

Other authors have shown other programs to be effective with children with asthma through such outcome measures as reduced emergency room visits, hospital use, sick days, and days lost from school.[6–10] Why have these other interventions been successful while this program was not? The inability of this intervention to demonstrate a reduction in ER utilization does not appear to be due to any of the following methodological problems: randomization problems, dropouts, exposure of control patients to intervention, omission of traditional program content, or accuracy of outcome measures.

TABLE 2—Respiratory-Related Utilization for Patients Enrolled Entire 1st 12 Months [N = 205]

	Experimental Group	Control Group
Number of Patients	101	104
Patient months enrolled	1212	1248
Number of ER visits	55	39
Distribution of ER visits		
0	77	86
1–2	17	13
3 or more	7	5
Hospital Days		
mean	0.27	0.22
standard deviation	1.34	0.74
Office Visits		
mean	1.63	1.86
standard deviation	2.28	4.24

The program probably failed for two sets of reasons: failures of implementation, and failures of program effectiveness. The socioeconomic, educational, and racial profile of the patients probably contributed to problems with both program implementation and program effectiveness. Programs need to be tailored to their target populations. Furthermore, the program was difficult to implement because it was offered to all eligible children with asthma, not just volunteers. This undoubtedly accounted for some of the difficulties in obtaining participation in classes by patients and parents. Implementation was further hindered by the enrollment of many patients with moderate asthma who were probably less motivated and less likely to benefit than patients with more severe disease.[11]

Problems with program effectiveness took several forms. The behavioral component of this program was less intensive than that of other successful programs.[6] It has been demonstrated for asthma[12] and other diseases[13–15] that increases in patient knowledge alone, without instruction on how to change behavior, will not improve patient compliance or health outcomes. Although the importance of behavioral change was discussed with patients in this program, specific behavior modification techniques such as reinforcement and contingency contracting were not utilized. Secondly, less mastery of the educational material was attained by the patients than anticipated, even though considerable resources were used in the program. Less mastery occurred partially because class attendance was less than expected. Furthermore, although telephone instruction alone improved the rate of contact and increased the level of mastery of certain educational objectives, it did not lead to the level of mastery desired.[5] Thirdly, those instructional sessions with parents alone may not have been as effective as those sessions including the children.

Although this study did not show any impact on health care utilization, it is possible that the intervention had a positive impact on functional measures such as days lost from school or sick days. These measures should be included in future research.

This study identifies problems that must be addressed during the widespread implementation and funding of patient education for asthmatic patients. To the inexperienced, patient education seems deceptively simple. However, unless the complexity of patient education is appreciated, a program may fail and may have unintended outcomes. The findings of this study suggest that programs should: 1) include a strong behavioral component, 2) be targeted at key groups who will actively participate and benefit, 3) be monitored to assure that intermediate goals are reached, and 4) be validated for specific socioeconomic groups before implementation.

ACKNOWLEDGMENTS

New NCHS Report Gives Trends in Low Birthweight

The National Center for Health Statistics recently released its latest findings in vital and health statistics. The report—*Trends in Low Birthweight: United States, 1975–85*—analyzes national and regional trends in rates of low, moderately low, and very low birthweight, and examines the relative risk by maternal characteristics such as age, race, education, and marital status. Some of the findings:

- Low birthweight (LBW) which had been on the decline for the past two decades, increased 2 percent between 1985–87.
- Approximately 262,000 LBW babies were born in 1987 (69 per 1000 live births).
- Rates of LBW and very low birthweight (VLBW) are substantially higher for Black than for White births. In 1987, Blacks were almost three times as likely as Whites to have a VLBW infant and more than twice as likely to have an LBW baby.
- Rates of low, very low, and moderately low birthweight (MLBW) are lowest for mothers in their late twenties and rise as maternal age increases or decreases.
- All LBW rates are substantially higher for young women having a second or higher order birth than for first-time mothers, reflecting the close spacing of many second and subsequent births.
- More than half of all LBW and MLBW babies and 90 percent of VLBW babies are born before 37 weeks of gestation (preterm). Of LBW babies who were full term, only 3 percent weighed less than 1500 grams, but 27 percent of those born preterm weighed this little. For both preterm and full-term LBW babies, the proportion weighing less than 1500 grams is higher for Black than for White babies.
- For all characteristics examined, rates of LBW, MLBW, and VLBW are substantially higher for Black than for White births. The racial differential is most pronounced for VLBW. In 1985, the VLBW rate was 2.8 times as high for Black as for White babies, and rates of LBW and MLBW were 2.1–2.2 times as high for Blacks as for White births.

Post-Hospital Support Program for the Frail Elderly and Their Caregivers: A Quasi-Experimental Evaluation

JULIANNE S. OKTAY, MSW, PHD, AND PATRICIA J. VOLLAND, MSW, MBA

Abstract: This paper evaluates the Post-Hospital Support Program for the frail elderly and their caregivers using a quasi-experimental design. The program goals were to reduce stress in the caregivers, improve functioning and reduce mortality in patients, and reduce health service utilization in patients. Subjects were patients at the Johns Hopkins Hospital in Baltimore, Maryland, age 65 or over, who were returning home to the care of a non-paid caregiver and who had extensive post-hospital care needs which were expected to continue for at least one year. The 93 comparison group patient/caregiver pairs were discharged between May 15, 1983 and May 14, 1984. The 98 treatment group pairs were discharged between May 15, 1984 and May 14, 1985. Interviews were conducted with patients and caregivers at 1, 3, 6, 9, and 12 months after discharge. Results showed a slight reduction in caregiver stress and a substantial reduction in hospital days used by the treatment group. When confounding and history effects are taken into consideration, an average difference of 6.5 days per patient remains. The data also suggest that the treatment program may have postponed some deaths and nursing home placements. The results suggest that support services for the frail elderly and their caregivers can be cost efficient by reducing hospital length-of-stay. Savings were estimated at $4,585 per patient per year in this study. However, further work is needed to design programs which more effectively reduce caregiver stress. (*Am J Public Health* 1990; 80:39–46.)

Introduction

The elderly population is expanding rapidly and, at the same time, growing proportionately older.[1] This means more and more elderly will be in need of some type of long-term care.[2] The cost for long-term care, especially for institutional care, has been growing considerably faster than the rate of inflation.[3] The $33 billion average annual expenditure (1986–90) for nursing home care is expected to expand to over $120 billion by the year 2020.[4] Nor are the projected increases limited to nursing home care. For every frail elderly person now in a nursing home, there are two equally frail elderly living in the community.[5] Providing home care services for this population is increasingly recognized as an important goal while, at the same time, the potentially explosive costs are greatly feared. A key to achieving good care for the community-based frail elderly population, and avoiding costly institutional care, is the family caregiver, who currently provides 80–90 percent of in-home care in the United States. The Informal Caregivers Survey, conducted as a part of the 1982 Long-Term Care Survey, showed that the typical caregiver of the frail elderly is a 57-year-old married female who is in poor health;[6] substantial proportions experience emotional distress and social isolation.[7,8] A number of programs designed to support these family caregivers have sprung up around the country, but most of them offer no more than a brief "support group"; these programs have not been systematically evaluated.[9] We do not yet know whether a program designed to provide support for the family caregiver can be effective in reducing the negative effects of caregiving, and whether this strategy will lead to a reduction in the use of institutional care. This paper describes a study designed to determine the effectiveness of a support program for caregivers of the frail elderly following hospital discharge. The program goals were to reduce stress in the caregivers, improve functioning in patients, reduce mortality in patients, and reduce cost by reducing health service utilization.

Method

Treatment Program

The Post-Hospital Support Program provided both medical and social services to the frail elderly and their families for one year following hospitalization. A coordinated approach was provided by a project team made up of a nurse and a social worker. Services included assessment, case management, skilled nursing, counseling, referrals, respite, education, support group, medical back-up, and on-call help. All cases received a minimum of one nurse and one social work visit per month. However, the amount of service depended on need. The service differed from what is usually available in the Baltimore area not only in the amount of service, but also in its coordinated medical-social approach. Focus was on the caregiver/patient configuration and not primarily on the patient; service was closely coordinated with the hospital inpatient and outpatient services; and service extended for one year post-discharge, regardless of the health status of the patient. Additional services were available, such as respite, some "gap filling" money (used primarily for incontinence supplies), and a support group. A more detailed description of the treatment program is provided in Appendix A.

Subjects

Subjects were inpatients at the Johns Hopkins Hospital who gave informed consent and who met the following eligibility criteria:

- Post-hospital care would be provided by a non-paid caregiver.
- Post-hospital needs were comparable to those of patients in "skilled" nursing facilities. (A measure, used by the State of New York—the DSM-1[10]—to determine eligibility for "skilled" care, was used to determine level of need. Patients with scores of 180 or more were eligible for the study.)
- Post-hospital care needs were chronic (expected to last at least one year) and long-lasting (patient expected to live at least one year).

- Patient residence was within 20 miles of the Hospital.

Design and Procedures

The design was quasi-experimental.[11] Patients who were discharged from the hospital between May 15, 1983 and May 14, 1984 constituted the comparison group; 93 patients and caregivers who met the eligibility criteria and agreed to participate during the first year of the study formed the comparison group. Patients discharged between May 15, 1984 and May 14, 1985 constituted the treatment group; 98 cases who met the eligibility criteria and agreed to participate in the second year formed the treatment group. The refusal rate was about 10 percent for both groups. Both patients and caregivers were interviewed within one month of discharge, and again at 3, 6, 9, and 12 months post-discharge. At the final interview, there were 50 patient/caregiver pairs in the comparison group and 62 patient/caregiver pairs in the treatment group. The interviews, which were identical for the two groups, were conducted by trained interviewers. Interviewers attended weekly supervisory sessions. Although there was no way to blind the interviewers, they were not aware of the pattern of the design, and did not seem to differentiate between comparison and treatment groups.

Measurement

Caregiver Stress—Caregiver stress was measured in three ways: The 27-item General Health Questionnaire (sensitivity = 88 percent, specificity = 84 percent)[12] was used to measure overall stress level. We also used a symptom checklist for measuring physical health (alpha = 82, inter-rater reliability = .88).[13] A measure of the extent to which caregiving was having a negative impact on the social functioning of the caregiver (Negative Impact of Caregivers Scale) was also included.[14] Finally, caregiver utilization of health services was measured with caregiver report.

Patient Functioning—Patient functioning was measured with the Katz Activities of Daily Living Scale (ADL)[15] (coefficient of reproducibility = .94–.98), three items* from the Instrumental Activities of Daily Living Scale (IADL)[16] (reproductibility = .94) and the Mental Status Questionnaire (MSQ)[17] (alpha = .84, test-retest reliability = .8). The ADL and IADL were based on caregiver report. The MSQ was given directly to the patient.

Patient Utilization of Services—At the 3, 6, 9 and 12 month interviews, utilization of a wide range of health services was determined (by caregiver report) including: physician and emergency room visits, nursing home days, use of home health nurse, home health aide, respite, transportation, social work, and other in-home services. In addition, hospital records were examined to determine hospital days used by the patient.

Data Analysis

Caregiver stress and patient functioning were measured with proportional change scores in each of the four time periods (0–3 months, 3–6 months, 6–9 months, and 9–12 months). That is, the time one score was subtracted from the time two score. This difference was then divided by the maximum change possible given the time one score. Thus if a patient scored "8" on the Mental Status Questionnaire, the maximum positive change would have been "2" because the maximum score on the scale is "10". If the change was negative, it was divided by the maximum negative change possible—in this case "−8". The resulting score ranges from −1 to +1. A score of "0" represents no change. "+.50" represents an improvement of 50% of the possible improvement, given the time-one score. The use of a proportional change score compensates for different amounts of possible change based on any uneven distribution of initial scores. All cases who were available at the two time points were included in the analysis. Thus a patient who died seven months after discharge would be included in the 0–3 and 3–6 month measures but not in the 6–9 or 9–12 month ones. Thus the number of cases decreases over the four time periods. A 0–12 month figure is also included for those who remained in the program for 12 months.

Mortality data are analyzed using the Mantel-Haenszel odds ratio for each of the four time periods and the total 12-month period. A Kaplan-Meier survival curve is also presented. In analyzing service utilization, descriptive measures (e.g., percents, means) are used for each of the time periods. For hospital days and outpatient visits, means are calculated for the entire group and again for the patients who stayed in the study for 12 months. This is to eliminate the effect of any differential mortality or institutional placement rates in the two groups.

Results

Sample Characteristics

The 191 patients in the study were predominantly female (61 percent) Black (76 percent) widowed (53 percent). The mean age was 76 years. Mean annual income was $3,880. One-third were on Medicaid; 63 percent had less than eight years of education. The mean DMS-1 score for the study population was 320. An example of a patient with this score would be Mr. L., "a 71-year-old man with coronary artery disease, diabetes mellitus, hypertension, permanent pacemaker, and glaucoma. He was admitted to the study after being hospitalized for left femoral peroneal bypass. He had extensive wounds extending from the groin to the achilles area requiring daily soaks, dressings and monitoring." In spite of this level of dependency, only 10 percent had poor prognosis; 52 percent had "guarded" or "fair" prognosis, and 38 percent had a good prognosis. The caregivers, 80 percent of whom were female, had a mean age of 53; 30 percent were spouses of the patient, and 35 percent were daughters; 73 percent had been caring for the patient before the hospital episode in which the patient was identified for the study.

Comparison of Treatment and Control Groups

The two groups were similar on most patient and caregiver demographic characteristics and on medical and functional status (Tables 1 & 2), with two exceptions. In the treatment group, more caregivers were new to the task, and fewer patients had a "good" prognosis.

Comparison of Services Received

In the Baltimore area, a variety of services were available to the comparison group during the course of the study. For example, home health service (limited to the period of skilled nursing need) including visiting nurse, home health aide, and social work services were widely available (Table 3). There was also a case management service (continuation of the program evaluated in the National Channeling Demonstration).[18] Transportation was available for Medicaid patients only. A comparison of the rates of service utilization

*The items were: handling the telephone, handling own medication, and handling own finances.

% on Medicaid	37.4	28.4
Demographic Characteristics of Caregivers		
% female	82.8	77.6
% of caregivers who are the spouse of patient	28.6	31.9
% of cases where caregiver provided care prior to the index hospitalization	60.4	83.7†

*Adjusted for inflation rate between 1983 and 1984 of 4.3 percent.
†Difference (60.4–83.7) = 23.3. 95% confidence intervals of the difference −35, −12.

TABLE 2—Medical and Funcational Characteristics of Patients in the Comparison and Treatment Groups

	Comparison Group (N = 93)	Treatment Group (N = 98)
Mean DSM-1, score	305.7	333.4
% of "Good" prognosis	46.2	29.6*
% Taking four or more medications	56.1	55.1
Mean ADL score on initial interview	5.0	4.3
Mean MSQ score on initial interview	5.5	6.1
Mean IADL score on initial interview	1.4	1.2
Mean # hospital days in year preceding	7.2	9.5

*Difference (46.2–29.6) = 16.6. 95% confidence intervals 3.6, 29.6.

in the comparison and treatment groups by caregiver report shows that, in all time periods, more patient/caregiver pairs in the treatment group received visiting nurse service and social work service, home health aids and transportation from the third to the twelfth month post-discharge, but not more respite care.

Impact on Caregiver Stress

A comparison of the proportional difference scores on caregiver stress for the treatment and comparison groups is shown in Table 4. Most of the proportional difference scores are negative, indicating a reduction in stress over time. The exception is on the Negative Impact on Caregiving Scale, which shows a sharp reduction in the 0–3 month period followed by a sharp increase in the 9–12 month period. Overall, the differences between the two groups are very small. The confidence interval includes zero for all but two comparisons: Number of Caregiver Illnesses (6–9 months) and Negative Impact of Caregiving (0–3 months). There is a consistent pattern of greater reduction in the General Health Questionnaire scores (indicating less mental disorder) for

TABLE 3—In-Home Service Utilization by Comparison and Treatment Groups at 3, 6, 9 and 12 Months Post Discharge

9–12 months	50	14	62	6	+8	+19, −36

treatment group caregivers, but none is large enough to inspire confidence.

No clear relations were found between prognosis and the caregiver stress variables. However, previous caregiving experience was found to be related to the proportional difference in caregiver illness at 6–9 months ($r^2 = .06$). (Those with prior caregiving had greater reductions in numbers of illnesses.) A pooled proportional difference score was calculated, based on the weighted scores of those caregivers who did and did not have prior experience. The pooled difference score was +.13, CI +.04, +.22. There is some evidence overall for a small treatment effect on caregiver stress.

Impact on Patient Functioning

A comparison of the proportional difference scores on patient functioning for the treatment and comparison groups is shown in Table 5. There is no evidence that the Post-Hospital Support Program had any effect—positive or negative—on patient functioning. Patients in both groups showed early improvement in Activities of Daily Living (ADL), followed by a leveling off. There was very little change in the Instrumental Activities of Daily Living (IADL) scores of either group. Both groups showed some improvement in mental status in the first part of the year, with a leveling off in the 9–12 month period.

Mortality

One year after hospital discharge, 27 patients in the treatment group had died (27.5 percent), compared to 28 in the comparison group (30 percent). While there is no evidence that the "Post-hospital Support Program" decreased

Total: 0–12 months	+.04	(50)	+.08	(62)	−.04	−.22, +.14

*On the ADL scale, a high score indicates that more assistance is needed with activities of daily living, hence, an undesirable outcome. On the IADL and MSQ indices, a higher score indicates better functioning.

mortality, there is some evidence that the program may have kept patients alive longer than those in the comparison group.

The Mantel-Haenszel odds ratios for four time periods show that, in the first nine months of the program, the odds of surviving were higher in the treatment group (OR 1.25 to 1.46). In the last three months of the 12-month follow-up period, the treatment group had slightly lower odds of surviving than did the comparison group (OR = .92). The

overall OR is 1.16. These differences are small, and the confidence intervals include an odds ratio of 0 in all time periods. A Kaplan-Meier survival curve (Figure 1) shows this pattern graphically. Thus, while we cannot conclude that the treatment program reduced mortality, the data suggest that some deaths may have been postponed.

Utilization of Health Services

Hospital Days—On the basis of the hospital charts, the patients in the study used an average of 33.9 hospital days during the study. This includes the index hospital episode where the patient was picked up for the study, which averaged 18.4 days. The index hospitalization is included because the PHS (post-hospital support) program began to impact on the situation well before discharge as PHS staff worked with hospital floor staff to plan for the discharge. Thus the program may well have impacted on the length of this initial hospitalization. Table 6 shows that there was a substantial difference in the number of days patients in the treatment and comparison groups were hospitalized. Patients in the comparison group averaged 38.5 days in the hospital (of which 21 days were for the index hospitalization). Patients in the treatment group were hospitalized an average of 29.1 days (of which 16 days were for the index hospitalization). Thus the patients in the Post-Hospital Support Program had fewer hospital days, both in the initial hospitalization and in the subsequent year. Because the mortality experience of the two groups was somewhat different, these averages were also calculated, excluding all patients who did not complete 12 months in the study. These results (line 4, Table 6) serve to strengthen the conclusion.

Because confounding was a possibility in this study, the potentially confounding variables ("good" prognosis and prior caregiver experience) were correlated with hospital days. Surprisingly, prognosis was not related to hospital days. However, prior caregiver experience showed a possible relationship ($r^2 = -.04$), suggesting that patients with caregivers who had been caring for them prior to the index hospitalization had fewer hospital days. Patients of caregivers with prior experience averaged 31.5 hospital days, compared to 39.9 hospital days for new caregivers. The pooled difference score in this case was 8.2 days CI +.7, +15, suggesting that the difference was not due to confounding.

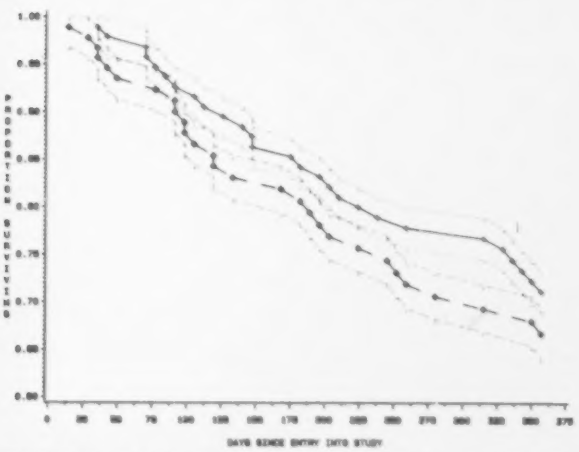

FIGURE 1—Survival Curves (with 95% confidence intervals) for Patients in the Treatment (PHS) and Comparison Groups

Treatment Group
95% confidence intervals for Treatment Group
Comparison Group
95% confidence intervals for Comparison Group

We conclude that the patients in the Post-Hospital Support Program spent fewer days in the hospital than did patients in the comparison group. The total difference averaged about eight days. About half of this savings was due to earlier discharges following the initial hospitalization. It seems probable that hospital staff were comfortable discharging patients with high levels of need earlier, knowing that a comprehensive support program would be available. However, the savings also continued in the year following discharge. The fact that there was no meaningful difference between the groups in the average number of hospitalizations (comparison group $\bar{X} = .66$, treatment group $\bar{X} = .78$) suggests that the same factor was operating in subsequent hospitalizations. Thus the treatment program probably did not prevent hospitalizations; it shortened them.

Table 6 also shows that the patients in the treatment program used fewer nursing home days than did those in the comparison group. However, the confidence interval is too wide to conclude that this difference was not due to chance. Since the proportion of patients who entered nursing homes was about the same in the two groups (12 percent in the comparison group, 10 percent in the treatment group), the difference in nursing home use is probably due to some postponement in entry. In fact, the mean number of nursing home days for those patients in the comparison group who entered nursing homes was 146, compared to only 86 for those who entered nursing homes from the treatment group. This represents an average postponement of about two months.

Not surprisingly, the treatment patients who were in the study at 12 months had slightly more outpatient physician visits than did those in the comparison group. This probably reflects some shifting of services from inpatient to outpatient.

Cost Implications

The Post-Hospital Support Program aimed to reduce costs by reducing unnecessary health service utilization. The figures presented in Table 6 have important economic implications. In order to estimate costs under the two conditions (treatment and comparison) average costs at the Johns Hopkins Hospital (or in the Baltimore area) during the study period were gathered. At the Johns Hopkins Hospital, the average cost of a hospital day in 1985 for patients over 65 years was $1,100. It represents an average of the more expensive first part of a hospitalization and the less expensive later part. This figure includes room, board, and medical services. The average nursing home ran about $65 per day. An outpatient visit averaged $50. Applying these figures to the data for Table 6, a 6.5 day reduction in hospital days means an average saving of $7,150. Eight less nursing home days represents a saving of $520. Two more outpatient visits means an extra cost of $100 per patient. This totals to a savings of $7,670 per patient per year.

This potential saving must be balanced against the program costs. The Post-Hospital Support Program actual costs averaged $4,584.67 per patient. While the cost of similar services to the comparison group are not as readily available, they can be estimated. Using the percents receiving visiting nurse services, we estimate 1.23 home health episodes per comparison group patient. Since an average home health episode at the Johns Hopkins Home Health Agency costs $1,116, the cost of home health services can be estimated at

TABLE 6—Utilization of Health Services by Patients in the Comparison and Treatment Groups

	Comparison Group Mean (std dev.) (a)	Treatment Group Mean (std dev.) (b)	Difference (a − b)	95% Confidence Interval of the Difference
Hospital Days				
Mean days in index hospitalization	21 (16.6)	16 (14.6)	+5	+.4, +9.6
Mean days in hospital from discharge to exit from study	17 (22.6)	12 (19.8)	+5	−1.4, +11.4
Total mean days in hospital (All cases)	39 (29.9)	29 (25.5)	+10	+1.6, +18.4
Total mean days in hospital (12 months cases only)	38 (30.5)	26 (25.3)	+12	+1, +23
Nursing Home Days				
Mean number of nursing home days	17 (59.3)	9 (32.9)	+8	−.56, +21.6
Outpatient Visits				
Mean number of outpatient clinic visits	5 (15.2)	7 (12.2)	−2	−1.9, +5.9
Mean number of clinic visits (12 month cases only)	8 (20.0)	10 (14.3)	−2	−3, −1

$1,372.68 per comparison group patient. Since we cannot calculate costs for transportation (received by 23–30 percent of the comparison group patients) or respite (received by 9–14 percent of comparison group patients), we will round the figure upwards to $1,500 to roughly account for these additional costs. Using this figure, the Post-Hospital Support Program cost about $3,085 more per patient per year. If we compare this to the $7,670 saved in the lower health service utilization, we see that there remains a cost saving of $4,585 per patient per year after additional program costs are taken into account.

Discussion

The Post-Hospital Support Program for the Frail Elderly and Their Caregivers was only partially successful in meeting its goals. There was evidence of some reduction in caregiver stress, but it was not impressive. There was no evidence of improved patient functioning. There was, however, a suggestion that the program may have postponed both deaths and nursing home placements. There was also a clear pattern of evidence suggesting that hospitalizations were shortened for treatment group patients, resulting in substantial cost reductions. These went well beyond the additional program costs.

Because our design did not control the threat of history to internal validity, we cannot overlook the fact that there were substantial changes taking place in the health care system during the course of the study. Because of the introduction of DRGs (diagnostic related groups) by the Medicare Program, hospital stays were being reduced for the elderly at this time.[19] It is possible that the reduction we observed was due to the difference between the years of observation (1983–84 vs 1984–85) rather than to the effect of the treatment program. However, the average reduction in hospital length of stay for patients 65 years of age and older between 1983 and 1985 was one day.† Since, in our study, patients had an average of 1.73 hospitalizations over the study period, we would have expected a reduction of 1.73 days on the basis of history alone. Since the difference we found was almost five times this large, it is highly unlikely that the prospective pricing system could have accounted for the differences found. Also because the 1.73 days related to all patients over age 65, and the patients in our study were a very frail subset of the over 65 population, the 1.73 day figure may well be high. Even if we subtract the 1.73 expected days shorter for the treatment group, we still find at least 6.5 days difference.

Because of the quasi-experimental design and the turbulent hospital environment which existed at the time of the study, the results should be subjected to more rigorous tests before firm conclusions are drawn.

The program's lack of success in reducing caregiver stress suggests a need to reexamine both the program offered and the assumptions behind it. Low attendance at caregiver support groups may have been due to program failure (e.g., lack of skilled leadership, of adequate transportation, or respite) or to a lack of interest in this type of service by caregivers. Recent results from respite programs for caregivers show similar findings,[20–22] suggesting that perhaps the whole notion of caregiver support needs to be reexamined.

In the Post-Hospital Support Program, there were frequent conflicts between the staff and patients/caregivers. These were usually because the staff wanted the medical regimen to be followed, or wanted a higher standard of

†Personal communication. Hyattsville, MD: Scientific and Technical Information Branch, National Center for Health Statistics, Nov. 1, 1987.

personal care to be provided, and these issues may not have been important goals for patients or caregivers. Also, when the interest of patient and caregiver conflicted, the staff tended to become advocates for the patient in spite of program goals. At staff meetings, staff frequently expressed frustration with caregivers who were not doing a "good-enough" job. It is possible that frequent visiting by this staff may have been more stress-producing than stress-reducing for caregivers. Another possibility is that the amount of support available may have been too small considering the nature of the task. One social worker told how she had spoken with a caregiver who complained that she was "so tired!" The social worker worked for several weeks to arrange help: some day care, home health aide and increased family help. When she called back to see how things were going, the caregiver again complained that she was "so tired!" Perhaps we need to examine in more depth the nature of the caregiving tasks, the interactions of patient, caregiver and agency,[23] and the psychology of mid-life women. This type of analysis may lead to the development of totally different types of "support" services.

A final note on caregiving. The current study underestimated the complexity of the caregiving situation. For example, the design designated one person as a "caregiver" and one as a "patient". In fact, a number of patients had multiple caregivers—sometimes sharing responsibilities, and sometimes caring for the patient in a "serial" pattern. In some situations, it was difficult to distinguish "caregiver" and "patient" as the year progressed. When two ill spouses care for each other, people shifted in and out of these roles as their illness waxed and waned. An index, such as the Negative Impact of Caregiving, was hardly appropriate when the designated caregiver was now in the patient role. The study results also suggest that the amount of previous caregiving experience was a critical variable. Future support programs would do well to consider what type of caregiver their services are aimed at. Programs for new caregivers might need to be quite different than those for long-term providers of care.

Although this was not the program's primary focus, the reduction in health service utilization suggested by the results is intriguing. It raises the possibility that the key to reducing hospital costs lies not in what happens in the hospital itself (e.g., discharge planning) but in what happens in the community. By strengthening the caregiver, the Post-Hospital Support Program may have allowed caregivers to take on even more responsibility. This may explain why stress levels were not reduced further.

The results are promising in that they suggest that programs designed to support the frail elderly population and their caregivers in the community can be cost efficient by reducing levels of health service utilization. However, further work is needed to design programs which are also beneficial to both patients and caregivers.

ACKNOWLEDGMENTS

An earlier version of this paper was presented to the 114th Annual Meeting of the American Public Health Association, Las Vegas, Sept. 28–Oct. 2, 1986. The research reported in this paper was supported by a grant from the Robert Wood Johnson Foundation. The authors thank Armen Thoumaian, Susan Nolt, Carol Sylvester, and Francis Lawrance for their contributions to the Post-Hospital Support Program.

APPENDIX A

Description of the Treatment Program

Treatment began in the hospital with assessments by both the Project nurse and social worker. At that point, an initial service plan would be established and caregiver education would begin. Because the initial adjustment to home care was often difficult, and patients were often very sick at this point, many patients needed frequent nursing visits in the weeks following discharge. If dressing changes were involved, up to three nursing visits a day were provided. Patients with complex medication schedules needed close monitoring and nurses helped caregivers to develop systems to simplify regimens and watched carefully to see the effects. Often they spent many hours communicating back and forth with the physicians until an appropriate medication schedule was established. If there were family problems, the social worker would become involved, helping families to develop caregiving patterns which they would manage. This often meant adding outside support. The Post-Hospital Support Program (PHS) made funds available for caregivers to hire helpers for personal care, monitoring, day care, and respite. The number of hours needed, and the supervision of outside help would be negotiated with the family, and an initial contract signed. Also, in rare cases, PHS would cover the cost of environmental modifications (e.g., bars, ramps, stair railings). Physical therapy was also provided if the staff thought it would be helpful, and it could not be covered by an outside payor.

After the initial adjustment period, each case received at least one nurse and one social work visit per month. In many cases, stable periods where only minimal assessment and monitoring were needed alternated with crisis periods, when very intensive levels of outside support were needed. The average was four nurse visits per month, and the maximum was a case which received 198 nursing visits in a year. The nurses carried a maximum of 20 cases, and the social workers 30 cases. If rehospitalization was needed, the staff would follow the patient's progress and prepare another plan for post-discharge care. Support group sessions were offered about once a month. Each session had a specific topic (e.g., "dementia", "handling caregiver stress") which opened with some prepared remarks by staff or invited speakers and ended with discussion among the caregivers. Food (usually lunch) was served, and respite and transportation arrangements were made to facilitate attendance. In spite of this, only a minority of caregivers attended those meetings (usually 10–15 caregivers). Meetings usually began with each of the caregivers introducing themselves and telling their "story". Each introduction was followed by an enthusiastic round of applause and many encouraging comments from the other caregivers (e.g., "Aren't you something!" "Your father is lucky to have you!" "You're doing everything you can.") Although not heavily attended, these groups sessions were real morale boosters for both caregivers and staff. Caregivers loved being treated "special" by the hospital. Staff enjoyed watching the caregivers interact, and they also received very heartfelt appreciation ("I don't know what I would have done without Ms. Gina [nurse]").

Throughout the duration of the program, a weekly staff meeting was held. This was attended by all staff nurses and social workers, a geriatric fellow, a psychogeriatric nurse, the researcher, and the project administrator. Each case was discussed on a periodic basis, but most of the time went to discussing problem cases, usually cases experiencing a medical crisis, or cases where the caregiving situation was deteriorating.

The program sought the best possible situation for each patient. Wherever possible, the staff tried to arrange things so that the patient could remain in the community as long as this was in the patient's best interest. In cases where the caregiving situation was poor, and did not improve in spite of repeated attempts to "prop it up" with education, added help and support, the staff would work actively to remove the patient from the home, even if it meant a nursing home placement. Although this type of situation occurred infrequently, deciding when a patient would be better off outside of the home was one of the most difficult aspects of the program for the staff.

As the end of the one year service period grew near, the staff arranged for a "discharge plan" which would provide ongoing care if needed. Those in need of skilled nursing care would be referred to Home Health Care services. Those who only needed somewhere to call if problems arose would be connected to a case-management service.

State Funding for AIDS Patient Care Increased 160% in 1989

State government funding for AIDS patient care in fiscal year 1989 totaled nearly $65 million or 26 percent of the total non-Medicaid state funds for AIDS, according to a report released October 17 by the George Washington University AIDS Policy Center. This represents a 160 percent increase from the $25 million appropriated in fiscal year 1988. Based on information from state officials nationwide, patient care will continue to absorb a significant share of state funds as the epidemic grows and more people become infected with the human immunodeficiency virus (HIV). Twenty-six states budgeted funds for at least one type of patient care service, whereas in fiscal year 1988, only nine states budgeted funds for that purpose.

Four states (California, Florida, Massachusetts, New York), allocated more than $5 million in state-only non-Medicaid funds for patient care programs for fiscal year 1989. Eight jurisdictions (District of Columbia, Georgia, Illinois, Louisiana, Maryland, Michigan, Missouri, Pennsylvania) appropriated $1–5 million.

The high cost of Azidothymidine (AZT) has prompted at least 10 states, including such low-prevalence states as Hawaii and Utah, to set aside funds to supplement federal allocations for AZT.

The AIDS Policy Center, a component of GWU's Intergovernmental Health Policy Project, is a legislative and policy research center that provides AIDS information and related research to legislators, policymakers and the media. This report, based on the Center's national survey of state AIDS funds released August 30, 1989, is the first of several analyses of states' allocation of non-Medicaid funds for various program areas. Other reports will examine education/information, testing and counseling, research, surveillance activities, support services and administrative activities. The survey and data analyses were supported by a grant from the American Foundation for AIDS Research (AmFAR). For a copy of this report, contact the AIDS Policy Center, (202) 676-8144.

Epidemiologic Features of Treated End-Stage Renal Disease in a Large Prepaid Health Plan

JUAN D. ORDOÑEZ, MD, MPH, ROBERT A. HIATT, MD, PHD, AND CHARLES P. QUESENBERRY, PHD

Abstract: We examined the incidence of treated end-stage renal disease (ESRD) among the two million members of the Kaiser Permanente Medical Care Program of Northern California from 1973 through 1985. The age-adjusted incidence rates rose from 33.9 to 81.7 per million person-years and showed no signs of stabilization. Rates were higher in men than in women and rose with age. Marked upward trends ($p < .001$) in the rates of treated ESRD associated with diabetic nephropathy and hypertension were noted. (*Am J Public Health* 1990; 80:47–49.)

Introduction

Since the enactment of Medicare legislation on end-stage renal disease (ESRD) in 1973, the cost to the United States government of caring for these patients has far exceeded expectations. The number of persons enrolled increased from 16,000 in 1974 to 99,000 in 1986, while the costs rose from $229 million to over $2.8 billion.[1]

Few reports document the incidence of ESRD in defined US populations, and those available from the Health Care Financing Administration (HCFA) have been limited by discontinuity in the data collection process[2] and lack of compliance with the patient history form.[1] Other regional studies encompass very short periods of time[3] or include no data on trends in incidence.[4–7]

This report describes the population treated for ESRD within the membership of the Kaiser Permanente Medical Care Program (KPMCP) of Northern California from 1973 through 1985. It is an extension of an earlier study derived from the same data sources for the years 1973 through 1977.[7]

Methods

The Kaiser Permanente Health Plan provides comprehensive hospital and inpatient services to subscribers and their dependents. The membership increased from 1.1 million in 1973 to about 1.9 million in 1986 and comprises about 25 percent of the population in the San Francisco Bay Area. The age distribution of the membership remained reasonably unchanged during the period of study. The demographic characteristics of this population in the San Francisco-Oakland Metropolitan Statistical Area are similar to those enumerated by the US census for the same area, except for some underrepresentation of persons in the extremes of the socioeconomic scale.[8] Dialysis and transplantation are generally subcontracted to outside providers.

Patient Identification

Patients were all health plan subscribers with ESRD treated with maintenance hemodialysis, continuous ambulatory peritoneal dialysis, or kidney transplantation from 1973 through 1985. Complete ascertainment was possible because patients requiring ESRD treatment were either treated at a dialysis unit in the Kaiser Permanente San Francisco facility or referred to external facilities through a central health plan office.

Medical Record Review

Medical records of all patients referred for ESRD treatment from 1972 through 1977 were reviewed in 1978,[7] those referred from 1978 through 1981 were reviewed in 1982,[9] and those referred between 1981 and 1985 were reviewed in 1986. In each study, methodology was similar. Medical records in all three periods were reviewed by a trained medical record analyst to obtain: demographic characteristics, renal diagnosis and date, whether a kidney biopsy was performed, date of referral for ESRD treatment, location of the referring facility and, when available, date of first dialysis.

Analysis

The date of first treatment was used to determine the annual age-adjusted incidence of ESRD. Only cases first treated after joining the health plan were included in the calculation of incidence rates. Rates were age-adjusted using the direct method with the 1980 US census used as standard. Time trends in the age-adjusted rates were examined using weighted least squares regression techniques.

Results

From 1973 to 1985, 1,134 patients were treated for ESRD, including 68 (6.0 percent) who were first treated before becoming health plan subscribers. Among the 1,066 diagnosed while subscribers (Table 1), the most common primary diagnoses were glomerulonephritis (25.4 percent), diabetic nephropathy (22.2 percent), primary hypertensive disease (13.4 percent), and polycystic kidney disease (7.9 percent).

The age-adjusted incidence rose in a continuous trend from 33.9 per million members in 1973 to 81.7 per million in 1985 (Figure 1). Although the most marked relative increase in incidence was among persons older than 65 years (40.0 per million in 1973 to 220.4 in 1985), the 15- to 44-year-old age group contributed the largest absolute number of patients (Figure 2).

A higher incidence in men was seen for all age groups after the first decade of life (Figure 3). The incidence in men increased steadily with age, in contrast to the incidence in women, which peaked in the 60- to 69-year-old age group.

Upward trends in the annual age-adjusted, disease-specific incidence were greatest for diabetic nephropathy ($p < .001$) and hypertension ($p < .001$). The incidence of polycystic kidney disease (PCK) increased slightly (trend, $p = .033$) and that of glomerulonephritis showed no evidence of a trend. The incidence of ESRD for all other diagnoses ranged between seven and 15 per million without any clear

Other	1.7 (10)	1.6 (14)	1.6 (24)
Unknown	13.0 (99)	3.9 (34)	8.3 (133)
Total	70.0 (610)	45.6 (456)	57.2 (1066)

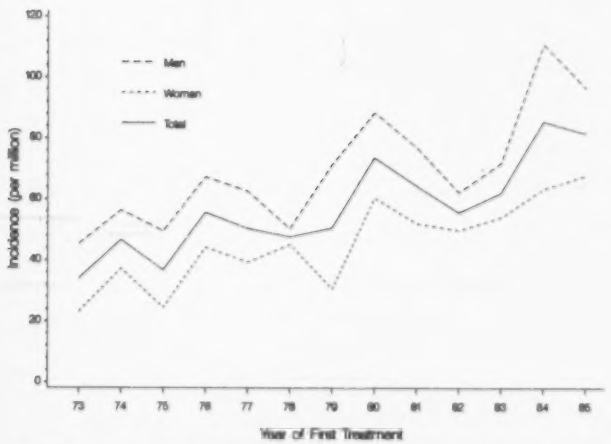

FIGURE 1—Annual Age-Adjusted Incidence of Treated ESRD in the KPMCP, 1973–85

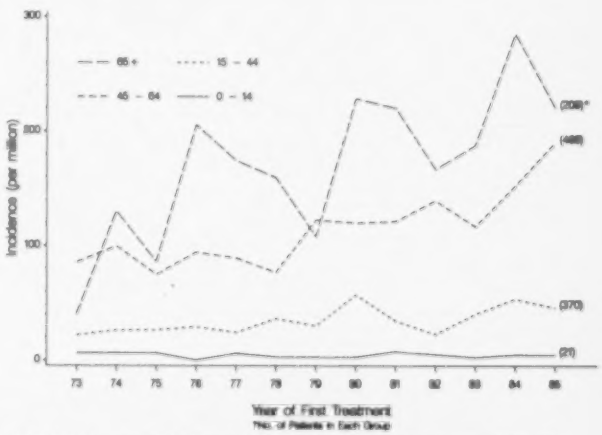

FIGURE 2—Annual Incidence of Treated ESRD by Age Group, 1973–85

trend over time.* The higher incidence of treated ESRD in the oldest age group (>65 years) was primarily associated with diagnoses of glomerulonephritis (23.4 percent) and hypertension (24.4 percent), whereas in the 45- to 64-year-old group, PCK and diabetic nephropathy comprised the largest proportion of patients (38.6 percent).

A small decrease occurred in the proportion of Blacks treated for ESRD in 1982–85 (18 percent), compared with 1973–77 (21 percent) and 1978–81 (24 percent). During the 1973–81 period, glomerulonephritis was the most frequent diagnosis among Whites and Hispanics (29 percent) and among Asians (46 percent) treated for ESRD; hypertension was the most frequent diagnosis among Blacks (26 percent). During the 1982–85 period, diabetic nephropathy became the most frequent diagnosis among all racial groups except Asians (Figure 4).

Discussion

The demographic characteristics of the patients treated for ESRD within the KPMCP in Northern California are similar to those in previous reports,[1,10] based on HCFA data. The incidence of treated ESRD in this health plan population has increased steadily from 1973 to 1985. This observation is compatible with those of Eggers, *et al*,[1] and Weller, *et al*,[11] and suggests that any conclusion that rates have stabilized[10] may be premature.

The most likely reason for the increasing incidence of treated ESRD is the continued liberalization of the criteria for the use of dialysis and transplantation by physicians, which is a consequence of improved survival and decreasing morbidity following treatment of ESRD in recent years.[12,13] Older patients with diseases more likely to be associated with systemic complications, such as diabetes and hypertension, may have benefited the most from the liberalization in criteria, because healthier patients were more likely to have been accepted for treatment in previous years. A possible increase in the incidence of insulin-dependent diabetes may also be contributing to the upward trend in incidence.[14] Finally, the improved medical management of diabetes and hypertension may have decreased competing mortality from coronary artery disease, thus increasing the number of diabetic patients reaching ESRD.

The higher incidence of treated ESRD in older age groups is compatible with the progression of chronic underlying processes that lead to terminal renal failure. The high

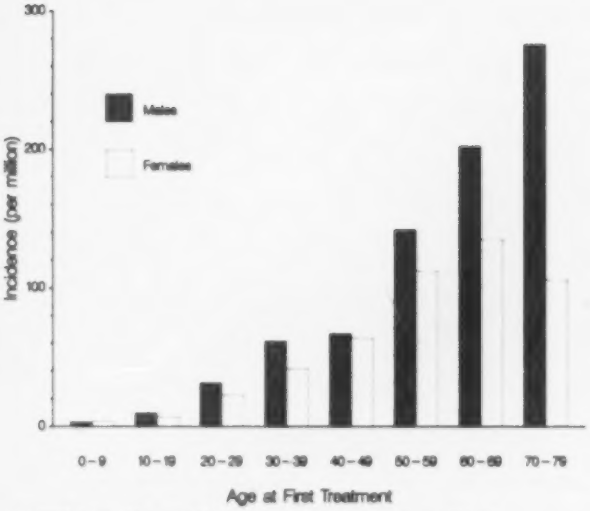

FIGURE 3—Incidence of Treated ESRD by Age and Sex, 1973–85

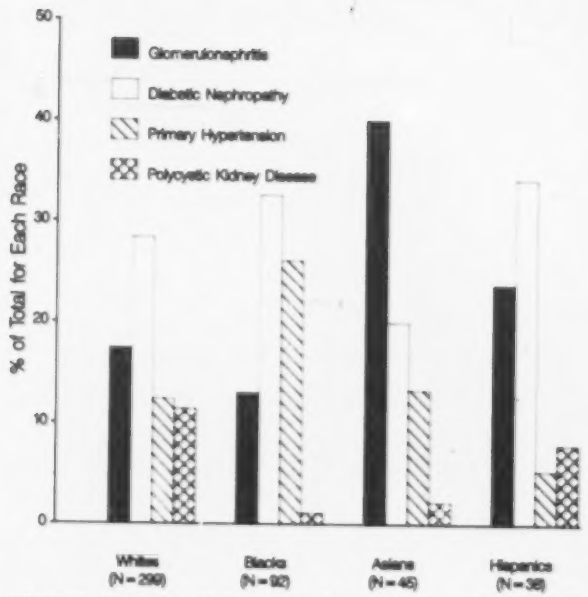

FIGURE 4—Distribution of Primary Renal Diagnosis among Treated ESRD Cases by Race, 1982–85

incidence noted in the group older than 70 years contrasts with national data from HCFA[1] and suggests that age may be less of a deterrent to use of hemodialysis among the KPMCP membership.

We were not able to calculate incidence rates by race because of the lack of data on racial composition of the health plan membership. However, the proportion of Blacks and that of Whites among those treated for ESRD may be decreasing in this Northern California population, while the proportion of Asians (and possibly of Hispanics) is increasing.[15] A higher incidence of diabetes has been reported among Hispanics, compared with other racial groups.[16]

An Epidemiologic Postmarketing Surveillance Study of Prescription Acne Medications

David P. Facklam, MS, Jacqueline S. Gardner, PhD, Gary L. Neidert, PhD, and Margaret M. Westland, MD, MPH

Abstract: After the Food and Drug Administration approved a topical antibiotic for the treatment of acne, we began a postmarketing surveillance study to measure the frequency of antibiotic-associated colitis and diarrhea in acne patients treated with topical antibiotics and low doses of oral antibiotics. Pharmacists recruited 13,465 patients who presented a prescription for an acne medication, and we obtained detailed information on the use of the medications, perceived acceptability, and the occurrence of new health events from 6,453 with computer-assisted telephone interviews. Three cases (<0.1%) of antibiotic-associated diarrhea and one case (<0.1%) of antibiotic-associated colitis were confirmed. We conclude that this methodology can provide further information about the safety of a drug once it is in customary use, at a fraction of the cost of Phase III clinical trials. (*Am J Public Health* 1990; 80:50–53.)

Introduction

In November 1981, the Upjohn Company's Medication Monitoring Program℠ initiated a postmarketing surveillance study of prescription acne medications. Prior to the initiation of the study, Upjohn introduced a topical clindamycin phosphate product (CLEOCIN T® Topical Solution) for the treatment of acne. Many other antibiotics are available for the treatment of acne. Since pseudomembranous colitis and severe diarrhea can occur with the administration of antibiotics,[1–6] with serious or even fatal consequences, it is important to measure whether the risk of developing colitis or severe diarrhea is increased in patients with acne being treated with topical antibiotics or low doses of oral antibiotics. Information from clinical trials, informal surveys, and case reports indicates that the risk in acne patients is rather low,[7–9] but estimates of the risk under normal use are lacking. We therefore conducted a postmarketing surveillance study to estimate the frequency of colitis and diarrhea in a sample of acne patients presenting prescriptions to pharmacies.

Methods

Recruitment of Pharmacies

A pharmacy-based model of postmarketing surveillance was developed by the Medication Monitoring Program.[10] Retail pharmacies, pharmacies associated with a dermatology clinic, university student health centers, and pharmacies on military bases were recruited to participate in the study, based on willingness to participate and medication dispensing profile. Fifty-eight pharmacies participated in the study, which represented a broad geographic distribution. Pharmacists were nominally reimbursed for their participation.

To create a registry of acne medication users from which to sample for further follow-up, we asked cooperating pharmacists to explain the study to all individuals who presented a prescription for an acne medication and invite them to participate. A total of 13,465 patients were registered by pharmacists and 10,282 (76.4 percent) signed a consent form agreeing to further follow-up and access to their medical records. Participation rates within pharmacies ranged from 9.3 percent to 100 percent and did not vary markedly by type of pharmacy.

Interviews

Participants were assigned different interview forms, based upon the drug or drugs on the registry, to save cost. Patients prescribed topical antibiotics were given the complete interview, which included patterns of use, assessment of acceptability and efficacy, and the occurrence of new health events (including non-hospitalized events, such as changes in bowel habits). Participants prescribed an oral antibiotic and any other prescription acne medication were randomly assigned to the complete interview module, to a short interview which collected only patterns of use, perceived acceptability, and the occurrence of hospitalizations and pregnancies, or to no interview.

A total of 9,965 (96.9 percent of 10,282) patients was assigned to receive two computer-assisted telephone-administered interviews: the first was scheduled five weeks following enrollment and the second was scheduled to be administered eight weeks later. The interviews were scheduled to cover the interval during which antibiotic-associated diarrhea or colitis would be most likely to occur if the patient was using the drug for the first time.[11]

If contact could not be made with the patient, a certified letter was sent to his/her last known address. The individual was asked to call the study collect or return a postcard indicating whether he/she still wished to participate. Patients who did not respond to the certified card were designated lost to follow-up and a questionnaire was sent to the enrolling institution or the prescribing physician. The questionnaire was used to determine last known vital status and whether the patient had been hospitalized during the follow-up period. No deaths were reported in this study. Of the 893 (9.0 percent of 9,965) patients lost to follow-up, 15 hospitalizations for 13 (1.5 percent) patients were reported. The mean age of those lost to follow-up was 22.7 years (range: 13 to 62 years); 60.3 percent were female.

A total of 8,304 (83.3 percent) patients completed the first interview (any module) (Table 1). Only data from the 6,453 patients who completed the full set of questions will be presented in this report. Patients were not paid for their participation.

The mean age of the participants was 22.9 years (range: <1 year to 80.6 years); 63.7 percent were female. The mean age of those not signing a consent form authorizing further follow-up was 23.4 years (range: 2.9 years to 78.1 years); 50.7 percent were female. Of all females registered, 80.2 percent

NOTE: This table includes only those registries in which patients agreed to participate in the study (76.4% of total registries).

agreed to participate compared to 72.8 percent of the registered males.

Investigation of Health Events

Hospitalizations, pregnancy outcome, and diarrhea requiring a physician contact were investigated further. A letter of inquiry was sent to the physician or institution requesting confirmation of dates, reasons for contact or hospitalization, and the final diagnosis. If insufficient information was returned, the report was referred to field investigation for resolution. The determination of the appropriateness of each investigated diagnosis was conducted by the medical monitor in a blinded fashion.

The criterion to define episodes of diarrhea was the patient report. No attempt was made to characterize the frequency or consistency of the stool. Clinically significant diarrhea was defined as that requiring contact with a physician and was investigated through the patient's physician. Patients who reported having the diarrhea at the time of the interview were contacted two weeks later and queried about the episode.

Results

Acne Medication Use

Multiple drug use was common, with individuals reporting an average of 2.6 acne drugs during the follow-up period. Of the 6,453 patients, 5,832 (90.4 percent) reported using at least one antibiotic during the follow-up period: 1,361 (23.3 percent) reported using only an oral antibiotic; 2,021 (34.7 percent) reported using only a topical antibiotic; and 2,450 (42.0 percent) reported using both an oral and a topical antibiotic.

Reports of Diarrhea

A total of 276 (4.3 percent) patients reported the occurrence of an episode of diarrhea during the follow-up period. The mean age of those reporting diarrhea was 23.8 years (range: 13.2 years to 53.4 years); 73.9 percent were female. A total of 4.8 percent of the female patients reported an occurrence of diarrhea compared to 3.3 percent of the male patients.

Of these 276 patients, 252 (91.3 percent) reported exposure to one or more antibiotics during the follow-up period. Table 2 presents the frequency of reported diarrhea by antibiotic exposure. Due to the large number of different types of antibiotics prescribed and the relatively small number of diarrhea cases, the exposure categories were collapsed to topical antibiotics and oral antibiotics. The rate of reported

*Patient may report multiple symptoms/factors
( ) % of number reporting diarrhea

diarrhea was slightly higher among users of topical antibiotic preparations than among users of oral antibiotics (RR = 1.5; 95% CI = 1.06, 2.13).

Further information was obtained about each reported episode. Table 2 shows the distribution of reported symptoms associated with the diarrhea by drug exposure. Blood and mucus in the stools were not asked separately. There were no significant differences in the frequency of reported symptoms associated with the diarrhea episode by antibiotic exposure. Patients were also asked whether they ever had diarrhea like this before, whether any individuals with whom they share living quarters had diarrhea around the same time, whether there had been any significant changes in diet prior to onset, and whether they had taken any trips prior to onset. The frequency of diarrhea reported by the season of the year did not vary significantly.

Twelve (0.2 percent) of 6,453 patients reported discontinuing a drug due to diarrhea; four patients discontinued oral tetracycline, two patients each discontinued topical clindamycin phosphate, oral erythromycin, and oral minocycline, and one patient each discontinued topical meclocycline and topical clindamycin HCL. Of the 3,811 patients exposed to at least one oral antibiotic, eight (0.2 percent) reported discontinuing an oral antibiotic due to diarrhea. Of the 4,471 patients exposed to at least one topical antibiotic, four (<0.1 percent) reported discontinuing a topical antibiotic due to diarrhea.

Eighty-two (1.3 percent) of 6,453 patients reported 85 contacts (visits or telephone contact) with a physician about the diarrhea episode. Confirmation of a diagnosis of diarrhea was obtained for 46 (54.1 percent) of the contacts. Three physician-confirmed cases of antibiotic-associated diarrhea included one case associated with tetracycline (oral), one case associated with erythromycin (oral), and one case associated with minocycline (oral). The causal association was based solely on the medical monitor's review of the physician's diagnosis obtained from the patient's records. No further confirmation of the diagnosis was obtained.

Colitis

Of nine (0.1 percent) patients reporting colitis, four of them reported no contact with a physician. Follow-up of the remaining five cases revealed only two cases of confirmed colitis, neither drug-related. Two other patients reported diarrhea, and follow-up with the treating physicians revealed oral tetracycline-associated colitis and stress-related colitis. Neither patient was hospitalized for the condition.

Hospitalizations

A total of 92 (1.4 percent) patients reported 93 hospitalizations during the follow-up period. The mean age of those hospitalized was 23.9 years (range: 11.1 years to 60.8 years); 63 (68.5 percent) were female. Table 3 presents a summary of the discharge diagnoses for 75 of the hospitalizations. Eighteen (19.4 percent) of the reported hospitalizations could not be confirmed. Two patients reported being hospitalized for diarrhea. One of the reports could not be confirmed and the discharge diagnosis for the other hospitalization was acute viral gastroenteritis.

Pregnancy

A total of 41 (1.0 percent) women reported being pregnant during the follow-up period. Their mean age was 24.8 years (range: 17.5 years to 34.3 years). Twenty-six (63.4 percent) of the deliveries were confirmed and four women volunteered that they had an abortion. Of the 26 confirmed births, 20 infants were normal, one infant was premature, one infant had hyperbilirubinemia, and the status of the remaining four cases was unknown. In all confirmed cases, the women reported discontinuing their acne medications during the pregnancy.

Discussion

This approach relies on the pharmacist or other pharmacy personnel to recruit patients. Probably not all patients who presented a prescription for an acne medication were invited to participate in the study; possibly invitation to participate was not random. For example, pharmacy staff may have invited patients only when they were not hurried or busy, or invited only patients who appeared friendly. We oriented the pharmacy personnel in person and frequently monitored their progress for significant variations. We did not audit the prescription records within each pharmacy, although a study in progress will do so. The impact of incomplete ascertainment or selection of only particular types of patients is unknown, but if the likelihood of invitation was not related to the medication prescribed, the comparisons of side effects among medications would not be affected.

We found that the patients used many other acne drugs that did not appear on the study registry. Since we designed the interviews to collect extensive information only about the registry drugs, we lacked important data about first time vs repeat use, length of prior use, dose and regimen.

The accurate determination of the presence of diarrhea is critical to the interpretation of the results. Stool collections or observations to accurately characterize the presence of diarrhea are generally not achievable in a general population-based study.[12] Daily diaries were thought not to be feasible due to the nature and the setting of the patient recruitment. We were left with the patient recalling the occurrence of diarrhea over a five- to eight-week period of time. We felt that clinically significant diarrhea would result in a contact with a physician and thus be available to the study by confirmation through medical records. Diarrhea serious enough to prompt the patient to seek a physician was confirmed in 46 (0.7 percent of 6,453) patients.

Despite some limitations imposed by the study design, our results are not substantially different from published data. Stergachis reported four cases of antibiotic-associated colitis that required hospitalization for treatment in a population of approximately 280,000 individuals.[13] We identified no cases of antibiotic-associated colitis that required hospitalization for treatment and one case of antibiotic-associated colitis that did not require hospitalization.

We conclude that while the occurrence of antibiotic-associated colitis and diarrhea appears to be rare in this patient population, appropriate education of the patient by the physician and the pharmacist to the potential side effects of treatment appears to be warranted.

Although epidemiologic postmarketing studies have been recommended to get further information about the safety of a drug once it is in customary use, few have been completed. We found pharmacist and patient cooperation to be high. Of the 10,282 patients who agreed to participate, we obtained complete data from 6,453 (62.8 percent). We initially assigned participants to long or short interviews to minimize the costs, but found the difference in the costs of obtaining complete information compared to partial information was inconsequential, once the patient was enrolled.

This methodology requires a sophisticated organization made up of epidemiologists, physicians, computer programmers, biostatisticians, and field personnel. Once the organization is in place, the cost of conducting a study such as this is very reasonable. Borden and Lee estimate that the cost of a study with this design is about 1 percent of that of the standard clinical trial.[10]

ACKNOWLEDGMENTS

We thank P.A. Zehner for the computer programming, P.J. Johnson for data handling, B.R. Brandow for manuscript preparation, and the field personnel for their follow-up and recruitment efforts.

AAAS Meeting to Feature Wide Range of Science, Medicine and Technology

A broad look at science—from the developing brain to exploring Mars—will be the focus of the upcoming 156th annual meeting of the American Association for the Advancement of Science (AAAS) when it convenes in New Orleans, Feb. 15–20, 1990.

Over 250 symposia will showcase what is happening in science and how that affects everyone. Among the topics featured will be neurotransplants, oil contamination in Prudhoe Bay, reducing the toll of natural hazards in the 1990s, exploration of Mars, progress in AIDS treatment, psychology of jury decision-making, climate change, chaos, effects of substance abuse on women, misconduct in science, physiology of exercise, computer viruses, and emotions and the developing brain.

A special feature of the meeting will be the inclusion of two separate three-day seminars on protein folding and the biology of parasitism; these symposia require an additional registration fee. Another feature of the meeting—"Public Science Day"—takes place on the opening day, February 15. The event will include workshops, demonstrations, and conversations with scientists. Public Science Day activities will feature programs to involve local students and their families in math and science. Also on Thursday, February 15, several thousand New Orleans area students will participate in a day-long "Science Encounters" program of lectures, demonstrations, and opportunities for young people to meet and talk with individual scientists and engineers. The AAAS Science and Technology Exhibition, February 16-19, will be at nearby Rivergate Exhibition Center. Poster sessions will also be featured adjacent to the exhibits.

The AAAS, formed in 1848, is the nation's leading general scientific organization, with more than 132,000 individual members and nearly 300 affiliated scientific and engineering societies and academies of science. For more information, contact AAAS, 1333 H Street, NW, Washington, DC 20005. Tel: (202) 326-6440.

Dependency on Soup Kitchens in Urban Areas of New York State

BARBARA S. RAUSCHENBACH, PHD, EDWARD A. FRONGILLO, JR, MS, FRANCES E. THOMPSON, PHD, ELIZABETH J.Y. ANDERSEN, BS, AND DEBORAH A. SPICER, MPH

Abstract: We studied the dependency of persons on soup kitchens in Albany, Buffalo, Rochester, Syracuse, and Westchester County, New York. Seventeen percent of the meal recipients were homeless, 62 percent lived in apartments or houses, 20 percent were working, 40 percent were women, and 17 percent had a child in their household. Fifty-nine percent started eating at the soup kitchen more than a year ago, and 51 percent ate five or more meals at soup kitchens in the last week. Most reported they came to the soup kitchen because of economic problems or lack of food; 93 percent had incomes below the poverty threshold. Most used some government food program; 48 percent received food stamps. Utilization of soup kitchens and other programs differed between men and women and between households with and without children. (*Am J Public Health* 1990; 80:57–60.)

Introduction

The number of meals served by a national sample of private emergency food programs increased by 21 percent from 1983 to 1984 and by 17 percent from 1984 to 1985.[1] In New York State, other than New York City, the estimated number of meals served monthly at soup kitchens was 204,334 in 1987;* this represents an increase from estimates for 1985 and 1986.[2] Other reports have documented the increased use of emergency food programs, discussed possible causes for it, and recommended policies to address the food needs of the users of emergency food programs.[3–6] However, there is little information about the people who are dependent on these programs.

This paper seeks to answer the following questions:

- What were the characteristics of persons dependent on soup kitchens in five urban areas of New York State outside of New York City?
- What was the extent of and reasons for their dependency on soup kitchens?
- What other food programs did they use?
- What were their perceived needs for health and other services?
- Were there differences in the patterns of dependency between men and women and between meal recipients who lived in households with and without a child?

Methods

Selection of Sample

In 1987 a survey was conducted of soup kitchens that served meals to the public during April in Albany, Buffalo, and Westchester County, and during October in Rochester and Syracuse. Of the 34 soup kitchens in these urban areas, 28 participated in the study.

It was not possible to take a random selection of guests from the sites because the total number of unduplicated guests who ate meals at the sites was not available. However, since the total number of meals served by the sites was available, meals were sampled, and the soup kitchen guests served those meals were interviewed. Because meals were sampled, guests who ate more meals at soup kitchens than others had a greater likelihood of being interviewed.

The goal was to select 20 meals at each site. An average of 17.9 meals were selected per site. Because an earlier study[7] found that soup kitchens served a greater number of meals at the end of the month, more meals (70 percent) were selected from the last half of the month.

A variety of mealtimes for interviewing guests was selected, and at each selected mealtime, the recipients of two or three randomly selected meals were interviewed. If the recipient was a child, the accompanying adult was interviewed. If a recipient refused to be interviewed, or if someone in his or her household had already been interviewed, the person next to that individual or the recipient of the next randomly selected meal was interviewed. Of the 501 soup kitchen guests interviewed, 87 percent were the recipients of the original randomly chosen meals.

Data Collection and Analysis

The guests were asked a series of primarily closed-ended questions about their demographic characteristics, household composition, sources and amounts of household income, use of health services, and use of other food programs. Each interview took about 25 minutes.

Unweighted frequency tables were created from the sample data and the chi-square statistic applied.[8] For the frequencies and means of the distribution of single variables, combined urban estimates were calculated from the sample data by combining site estimates so as to weight for the number of meals served in each site and in each urban area, assuming that the guests at nonparticipating soup kitchens were similar to those at participating soup kitchens. The combined urban estimates represent the monthly total of soup kitchen meals (82,449) served in the five urban areas.

To estimate variances and standard errors, and to study the implications of varying sampling designs, the betabinomial distribution[9,10] was used to model percentage estimates. The method of moments[9] was applied to 37 dichotomous variables and adjusted for the finite population of sites.[11] Analysis of variance was used to determine what proportion of the among-site variance was due to within-city and among-city variances.

To determine to what degree the results based on a sample of meals could be generalized to the population of soup kitchen guests, estimates were recalculated for those variables related to the probability of a guest being selected into the sample, i.e., each response was multiplied by the

reciprocal of the number of times each guest had eaten at soup kitchens in the last week. Responses for those who ate more than 10 meals were weighted by 1/10 so as not to underweight the responses of frequent users.

Results

For 34 of the 37 variables analyzed using the betabinomial distribution, more than half of the total variance was due to the among-site variance. The standard errors estimated from the percentages in the total sample ranged from 1.1 percent to 2.9 percent. Therefore, 3 percent can be considered as a general (conservative) estimate of the precision of the percentages reported in this paper. The variation within cities was found to be greater than the variation among cities. For 26 of the 37 variables examined, the among-city variance was zero. For the remaining 11 variables, the ratios of the among-city variance to the within-city variance ranged from .07 to .45, indicating that the among-city variance was at most less than one-half the size of the within-city variance.

When the estimates based on meals were compared to the new estimates based on people, only five variables had estimates that differed by 5 percent or more. The estimates based on meals were larger than those based on people for eating at another soup kitchen (21 percent vs 12 percent) and homelessness (17 percent vs 12 percent), and smaller for women (40 percent vs 45 percent), children in the household (17 percent vs 22 percent), and another adult in the household (12 percent vs 25 percent). Therefore, except for these few variables, the reported estimates for the population of soup kitchen meals can also be interpreted as estimates for the population of soup kitchen guests. Throughout the rest of the paper, the results based on the sample of meals are reported for meal recipients.

- *Who was dependent on soup kitchens?*

Demographic Characteristics

The majority of the meal recipients were men (60 percent). The average age of meal recipients was 43.6 years and 20 percent of them were 60 years old or older. Most of them were White (65 percent) although 29 percent were Black. Their educational attainment was generally low; 52 percent did not have a high school diploma. Most of the meal recipients lived alone or in a shelter or group home (70 percent).

Employment

Only 20 percent of the meal recipients were employed. Although 37 percent of the unemployed were looking for work, many of the unemployed were disabled (32 percent), retired (19 percent), raising a family (11 percent), or attending school or a training program (5 percent). Meal recipients who were employed earned on average $5.47 per hour and held labor (45 percent) and service (30 percent) positions (Table 1).

Income

Ninety-three percent of the meal recipients' household incomes in the previous month were less than 100 percent of the poverty level and 55 percent were less than 50 percent of the poverty level (Table 2). The most frequently reported sources of household income were public assistance other than Aid to Families with Dependent Children (AFDC) and work relief (28 percent), Supplementary Security Income (SSI) (22 percent), Social Security (22 percent), and wages (21 percent).

TABLE 1—Types of Employment of Soup Kitchen Meal Recipients*

Type of Employment	Examples	Percentage of Meals for Those Employed
Laborer	Day labor, collecting bottles and cans, odd jobs	45
Service	Household worker, wait person, janitor	30
Operative	Delivery person, cab driver, assembly worker	16
Clerical	Teacher's aide, clerk, secretary	7
Crafts person	Carpenter, mechanic	7
Professional/Manager	Substitute teacher	3

*These percentages do not add to 100 because more than one response was possible. Ninety-six sampled meal recipients responded to this question.

TABLE 2—Household Income of Soup Kitchen Meal Recipients in Previous Month

	Percentage of Meals
Monthly Household Income (does not include food stamps)	
$0–150	27
$151–300	22
$301–600	41
$601–$1000	7
$1001 +	4
Average (mean) per person household income $275	
Sources of Household Income	
Other public assistance	28
Social Security	22
SSI	22
Wages	21
AFDC	9
Work Relief	9
Retirement	4
Veterans' disability	2
Workers' compensation	2
Unemployment	2
Child support	1

*These percentages do not add to 100 because households received income from more than one source.

Housing

The problems that bring people to soup kitchens affect a broader segment of the population than just the homeless. Sixty-two percent of the meal recipients lived in apartments or houses. Only 17 percent were homeless—persons who nad lived in a shelter (11 percent), or on the streets or in no one place (6 percent) during the previous month,** and 20 percent lived in a room or group home. However, other indications of housing instability were that 15 percent of the meal recipients had moved since the month before, and 7 percent were living with unrelated people.

Thirty-one percent of the meal recipients who lived in apartments, houses, or rooms had housing that was partially subsidized or paid for by the government. It was not clear what portion of the rent of guests with subsidized housing was subsidized. However, for those without subsidized

**This percentage would have been greater if soup kitchen sites that served meals only to residents of their shelters had been included in the sample.

housing, the average monthly household rent was $193 and comprised 57 percent of the average household income.

- *What was the extent of and reasons for dependency on soup kitchens?*

Soup kitchen meal recipients tended to use soup kitchens often and over a long period of time. Fifty-one percent of the meal recipients had eaten five or more meals at soup kitchens during the previous week, and 59 percent had started eating at the soup kitchen more than a year ago.

The most common reasons that meal recipients gave for eating at the soup kitchen were the need for food (71 percent), including such reasons as no place to cook and nowhere else to eat, and economic problems (48 percent), such as no money (Table 3). Eighty-nine percent gave at least one of these reasons. However, 41 percent of the meal recipients also gave social reasons such as the need to be among people and the support of the soup kitchen staff.

- *What other food programs were used by soup kitchen meal recipients?*

Public Programs

Government food programs were used by almost two-thirds (64 percent) of the meal recipients' households, and many of these households received food from more than one program. Forty-eight percent of the soup kitchen meal recipients' households received food stamps in the previous month, 54 percent of the meal recipients whose households did not receive food stamps had received food stamps sometime in the past, 8 percent had applied for food stamps but did not receive them, and 38 percent had never applied for them.

Meal recipients' households that received food stamps received on the average $80 in food stamps in the previous month, and 96 percent of them had household incomes that were below poverty level even when the value of their food stamps was included as income.

Forty-two percent of the meal recipients' households had received food from a free food, cheese, or other government surplus distribution in the previous month. Of those meal recipients' households who may have been eligible for the program, 29 percent received food from a senior center, 57 percent received food from a free or reduced price school breakfast, and 66 percent from a free or reduced price school lunch program, and 37 percent received the Special Supplemental Food Program for Women, Infants, and Children (WIC) benefits.

TABLE 3—Meal Recipients' Reasons for Using Soup Kitchens[a]

Reasons	Example	Percentage of Meals
Food	No food, no place to cook, don't know how to cook, special diet, nowhere else to eat/go	71
Economic reasons	No job, waiting for public assistance, no money	48
Social reasons	Love the people here, get out, lonely	41
Program	Shelter, religious services, referred to program, to get help, volunteer	12
Convenience	Close by, kill time, break monotony, other site closed, save time on cooking	11
Miscellaneous	Family difficulty, medical problems, for exercise, old	4

[a]These percentages do not add to 100 because meal recipients gave more than one reason.

Private Programs

Many meal recipients had received food from other private food sources in the previous month: food pantries (33 percent), shelters that served meals only to residents (9 percent), and credit from a grocery store (3 percent).

- *What were the meal recipients' perceived need for other services?*

Housing

Many of the meal recipients lived in housing that lacked basic facilities. Sixty-one percent of the meal recipients did not have access to a phone, 29 percent did not have access to a working refrigerator, and 28 percent did not have access to a working stove or range.

Health Services

The most frequently mentioned forms of health insurance were Medicaid (56 percent) and Medicare (21 percent). Twenty-three percent of the meal recipients had no health insurance, and 19 percent reported their families had medical expenses in the previous year that were not covered by insurance. More of the meal recipients reported a need for dental services that their family could not afford (18 percent) than a need for medical services (6 percent).

Access to Food

Fifteen percent of the meal recipients had difficulty getting to a grocery store; 11 percent had problems with transportation, and 7 percent had health or mobility problems that made it difficult for them to get to a store.

- *What differences were there in the dependency of subgroups of guests?*

Reports that have noted an increase in soup kitchen use have also noted an increase in the number of families with children eating meals at soup kitchens.[1,3,4] In the cities included in this study, 40 percent of the meal recipients were women and 17 percent of the meal recipients' households included children.

Men vs Women

The men and women eating meals at soup kitchens differed in that women were more likely to have health insurance (86 vs 75 percent), to have received AFDC (17 vs 1 percent), or SSI (31 vs 20 percent), and to have received food stamps (64 vs 39 percent), surplus foods (58 vs 38 percent), and food from a food pantry (44 vs 32 percent). Men had an average per person household income of $328 compared to $255 for women. Men were more likely to have received food from a shelter in the previous month (15 vs 6 percent), and ate more frequently at soup kitchens in the previous week (4.7 vs 3.2 meals).

Guests Living with and without Children

Soup kitchen meal recipients who lived with children were on average younger than meal recipients who did not live with children (35.7 vs 46.5 years), had lower average per person household incomes ($146 vs $330), were less likely to receive Social Security (12 vs 29 percent) and were more likely to receive AFDC (37 vs 1 percent), other public assistance (36 vs 25 percent) and food stamps (74 vs 43 percent), and were less likely to eat at shelters (2 vs 14

percent). They had on average eaten fewer meals at the soup kitchen in the last week (2.8 vs 4.4) and had been eating at the soup kitchen for a shorter period of time (16.7 vs 23.0 months).

Discussion

For future studies of soup kitchen meal recipients, the large among-site variance suggests that sampling from more sites could reduce the variance of estimates. For example, given a population with 100 sites, the standard error of an estimated percentage based on a sample of 40 meal recipients from five sites would be about 11 percent compared to only 6 percent for a sample of 10 meal recipients from 20 sites.

A variety of people other than single, homeless, males were found to eat at soup kitchens. Subgroups differed in their use of soup kitchens, their use of other programs, and their resources. Men and guests who do not have children in their households may be less likely than others to be, or perceive themselves to be, eligible for government benefits and other programs or more likely to prefer to eat at soup kitchens. Whether the goal is to reduce the number of people having to use soup kitchens or to serve the unmet needs of soup kitchen guests, differences in the utilization of programs among these subgroups should be kept in mind.

We also found that a large number of soup kitchen meal recipients ate often at soup kitchens and had been eating at them for a long period of time. To the degree that guests do not use soup kitchens as a source of "emergency food" but eat at them often and over a long period of time, more attention needs to be given to the nutritional quality of soup kitchen meals.[12]

Over one-half of the meal recipients had no access to a telephone and 18 percent stated their families needed dental services which they could not afford. The use of a telephone is an important resource for obtaining employment as well as interacting with social services to apply for and receive benefits. Neglected dental problems may interfere with soup kitchen guests' abilities to eat adequate diets.

Many soup kitchen meal recipients were participating in government food programs, such as food stamps, and still eating at soup kitchens. This suggests that government food programs may not provide all persons with sufficient resources to obtain enough food. Most of those receiving food stamps reported incomes below the poverty threshold even when their food stamp benefits were considered as income. Many of the meal recipients gave a social reason as one of their reasons for coming to the soup kitchens. Participation in a government food program, such as food stamps, may not substitute for the feeling of belonging and the social support that many soup kitchen guests receive at soup kitchens.

More research is needed on soup kitchen meal recipients to determine: why more than one-half of them were not using food stamps; how housing problems other than homelessness, such as the cost of housing and the lack of basic facilities, e.g., a refrigerator, limit their access to food; and what other services are needed besides meals to improve their situations.

The findings from this study of soup kitchen guests indicate that any policies or programs to address the needs of soup kitchen guests must look past oversimplified views of soup kitchen guests, e.g., the homeless, singles, males, persons who have not accessed public programs, or persons who are eating at soup kitchens because of a temporary emergency. Soup kitchen guests include a variety of persons with a variety of patterns of and reasons for dependency on these programs.

ACKNOWLEDGMENTS

This research was conducted in the Division of Nutritional Sciences, Cornell University, under a contract with the New York State Department of Health, Bureau of Nutrition.

We would like to thank the soup kitchen guests who agreed to be interviewed, directors and staff at the participating soup kitchens in Albany, Binghamton, Buffalo, Rochester, Syracuse, and Westchester County and at Loaves and Fishes in Cortland, Loaves and Fishes in Ithaca, and the Rescue Mission in Syracuse.

We would like to acknowledge the assistance of the interviewers and the interviewer coordinators, Helen Urban, Tamera Lockwood, Nancy Johnson, Jackie Dockstader, Kathy Simpson, and Joanne Foulk. We would also like to thank Dr. Janice Dodds in the Bureau of Nutrition, the Regional Public Health Nutritionists, Joanne Stahl, Barbara Krueger, Donna Farlow, Sandra Rhoades, and Lynn Perton, faculty within the Division of Nutritional Sciences, and Patty McGrath-Morris, Janet Weber, and Mary Arimond.

Predictors of the Initiation of Psychotherapeutic Medicine Use

ALISON M. TRINKOFF, ScD, JAMES C. ANTHONY, PhD, AND ALVARO MUÑOZ, PhD

Abstract: This study examined the hypothesized predictive association between illicit drug use and the onset of prescribed psychotherapeutic medicine use. The effect of psychiatric symptoms on this relationship was also explored.

Data were gathered retrospectively, through standardized household interviews conducted in 1981 for the Baltimore site of the National Institute of Mental Health Epidemiologic Catchment Area Program. For this analysis, the sample was restricted to 1,716 respondents ages 18–44 at the time of interview, drawn by probability sampling area household residents of all adult ages. Using Cox proportional hazards models, the onset of psychotherapeutic medicine use was modeled as a function of illicit drug use and psychiatric symptoms, both defined as time-dependent covariates. Newly observed in this analysis was an independent association of illicit drug use with psychotherapeutic medicine use, which was unexplained by psychiatric symptoms (relative hazard = 2.61, 95% confidence interval (CI) = 2.15, 3.18). Adjustment for age of onset of alcohol intoxication did not alter the impression that illicit drug users were more likely to initiate use of prescribed psychotherapeutic medicines (relative hazard = 2.52, 95% CI = 2.02, 3.11). (*Am J Public Health* 1990;80:61–65.)

Introduction

Studies of drug sequencing have focused on detecting patterns in the age of onset of drug and medicine use among adolescents and young adults.[1–3] This research has identified a modal sequence of onset beginning with alcohol and cigarette use, followed by marijuana use, and then use of other illicit drugs. In one of the latest studies on this issue,[4] initiation of marijuana use was found to precede initiation of prescribed psychotherapeutic medicine use.

Based on these results, researchers hypothesized[5,6] that there might be a relationship between illicit drug use and psychotherapeutic medicine use. Yamaguchi and Kandel reported that illicit drug use increased the risk of initiating psychotherapeutic medicine use, using retrospective reports of the age of onset of different types of drug use. They then showed that the presence of depressive symptoms reduced this relation between the substances among women but not among men. Other studies lending support to the potential for symptoms to act as an explanatory link are those which found that relief of symptoms was a major reason given for use of illicit drugs [7,8] and those that show a direct relation between psychotherapeutic medicine use and psychiatric distress measured cross-sectionally.[9–12]

In addition to the role that psychiatric symptoms or distress may play in influencing the use of illicit drugs and psychotherapeutic medicines, other possible etiologic mechanisms have been suggested. Raveis and Kandel [13] proposed that a change in substances used over the lifespan may be part of a maturation process that coincides with the assumption of adult roles, such as establishing a residence, beginning a job, and marriage. In a study of young adults during the three years after high school graduation, Bachman, *et al*,[14] found that illicit drug use decreased from high school levels for those who were married, increased for those who were single and living away from home, and was unchanged for those who remained with their parents.

Drug use also may be understood as a learned behavior, in which reinforcing consequences of illicit drug use later influence the taking of prescribed psychotherapeutic medication.[15] Further, in a study by Newcomb, *et al*,[16] illicit drug use was correlated with deviance and with a sensation-seeking trait in adolescents, both of which could account for a relation between illicit drug use and prescribed psychotherapeutic medicine use.

In this study we hypothesized that if the data were to support such a relation, this would be due to the effect of psychiatric symptoms, such as anxiety or depression, on both forms of drug use. We also explored the effect of the sequence of onset of illicit drug use and psychiatric symptoms upon the initiation of psychotherapeutic medication. This allowed us to compare individuals who experienced symptoms prior to illicit drug use with individuals who used illicit drugs and then developed symptoms, in terms of their likelihood of subsequent psychotherapeutic medicine use. Sociodemographic variables that may influence the occurrence of psychotherapeutic medicine use were treated as potentially confounding or modifying covariates.

Our study expands upon prior research in this area by its use of a more heterogeneous sample with a wider age range, and by broadening coverage of psychiatric symptom categories as opposed to earlier research in which only one symptom category, such as depressive symptoms, was measured. Furthermore, incorporation of age of onset data into the analyses, for the first time allows us to examine the effect of sequence of onset of symptoms, illicit drug use, and prescribed psychotherapeutic medicine use.

Methods

Study Sample

The study sample consisted of subjects selected for the Baltimore site of the National Institute of Mental Health Epidemiologic Catchment Area Program. The details of the survey design have been reported elsewhere.[17] Briefly, the population from which the sample was drawn was comprised of adult household residents of the Eastern Baltimore Epidemiologic Catchment Area (ECA), approximately the eastern one-third of Baltimore City. Respondents were chosen for inclusion in the sample using area probability sampling. Household residents eligible for selection were all persons ages 18 or over at the time of contact in 1981, with the ECA defined as their usual place of residence. The survey completion rate for designated respondents ages 18–44 ranged

from 88–93 percent for race other than White and 80–89 percent for Whites.[17]

Of the 3,481 people interviewed, all subjects ages 18–44 at the time of interview were included in the present analysis (n = 1,716). The upper age limit for inclusion in the study was 44 years, since onset of illicit drug use after this age was quite rare.[18] The sample consisted of 1,048 females (61 percent) and 668 males, with 916 Whites (53 percent), 746 Blacks (44 percent), and 54 (3 percent) of other races. Seventy-six percent of the sample was in the married or single categories at the time of interview, and 45 percent had annual household incomes under $15,000. Twenty-seven percent of the respondents reported that they had sought help for a nervous or emotional problem at least once in their lifetime.

Study Variables

Information on the study variables was obtained from standardized interview questions covering demographics, health services utilization, the Diagnostic Interview Schedule, and a detailed survey of medicine use. Detailed information on the survey interview has been published in a monograph.[17]

Psychotherapeutic medicines were defined as those used primarily to treat, control, or prevent mental and behavioral disturbances, or to alleviate symptoms of psychopathology. Included in this definition were prescribed anti-psychotic agents, anti-anxiety agents, anti-depressants, stimulants, daytime sedatives, and hypnotics. Excluded were medicines with some psychotherapeutic action that are primarily prescribed for other purposes, such as analgesics, and over-the-counter medicines. Respondents were considered to be positive for psychotherapeutic medicine use if they stated that they had taken any medicines included in the above definition one-or-more times. The age of onset of psychotherapeutic medicine use was defined as the age at which a respondent first used a psychotherapeutic medicine.

Illicit drug use was defined as any use of drugs to get high, or without a prescription, or in greater quantity than was prescribed. Drug categories included marijuana, amphetamines, barbiturates, tranquilizers, cocaine, heroin, methadone, opiates, and psychedelics, with age of onset of illicit drug use defined as the reported age at which a respondent first engaged in illicit drug use. Age of onset of illicit drug use was distinguished from age of onset of psychotherapeutic medicine use by means of specific decision rules (see Data Analysis).

Data on psychiatric symptoms were obtained using the Diagnostic Interview Schedule. The term symptom was used to denote either the presence of psychiatric symptoms or a discrete spell of psychiatric disturbance occurring at any time in the respondent's life. Symptoms included were nervousness, delusional thoughts, hallucinations, pathologic worry, compulsions, and phobias. Spells included depressive spells, manic spells, and anxiety and panic attacks. The age of onset of a psychiatric symptom or spell was defined as the reported age at which a symptom or spell was first experienced. For individuals experiencing more than one category of symptoms, age of onset was defined as the youngest age at which the respondent reported onset of a symptom.

Data Analysis

Analyses were conducted using Cox proportional hazards models for censored survival data, with illicit drug use and psychiatric symptoms defined as time-dependent covariates.[19–21] Since time (t) in this analysis was defined as chronological age, all models were carefully age-adjusted as suggested by Breslow.[20] Illicit drug use occurring prior to the onset of psychotherapeutic medicine use was coded as zero until the age of onset of such use, at which point it was coded as 1. Thus, for the covariate illicit drug use, a subject would have a value of zero for every age until an illicit drug was used. If an illicit drug was first used at age 18, the subject would have a value of 1 for illicit drug use beginning at age 18 and continuing from that age onward. Psychiatric symptoms were treated in the same way. Subjects who had not used a psychotherapeutic medicine by the time of interview were treated as censored observations.

Forty-five respondents reported the same age of onset for illicit drug use and psychotherapeutic medicine use. This led us to be uncertain about whether prescribed psychotherapeutic medicines had been used illicitly by these respondents. To address this uncertainty we conducted analyses in two ways: first, these individuals were counted as positive for illicit drug use and second, as negative for illicit drug use. There was little difference in the results of these two approaches. In this paper we present the results of the second approach.

In addition to adjustment for age, models were also adjusted for other fixed covariates selected as a result of the heterogeneity with which they were distributed over psychotherapeutic medicine use in the study data, and from evidence from prior research on psychotherapeutic medicine prevalence.[22–28] Fixed covariates were defined as follows, with reference categories in parentheses: race = (Black)/other; sex = (male)/female; marital status = (married)/never married/widowed/separated-divorced; annual household income = <$15,000/$15–19,999/$20–24,999/($25,000+); and help-seeking = yes/(no). Help-seeking was defined as ever having sought help from a professional or a provider for a mental health, nervous or emotional problem, or for problems with alcohol and drugs.

For the purposes of analysis four models were fitted. Model 1 tested for the existence of a predictive association between illicit drug use and psychotherapeutic medicine use in the presence of the fixed covariates. Model 2 tested the hypothesis that the association between illicit drug use and psychotherapeutic medicine use, if present, could be accounted for by the existence of psychiatric symptoms. This was accomplished by entering the term for symptoms into the model, along with illicit drug use and the fixed covariates. Model 3 added an interaction term to Model 2, to test for a possible interaction between psychiatric symptoms and illicit drug use in relation to psychotherapeutic medicine use. Model 4 examined the effect of the sequence of onset of symptoms and illicit drug use on psychotherapeutic medicine use. In particular, Model 4 took the form:

$$h(t) = h_o(t)\exp[b_1x_1(t) + b_2x_2(t) + \gamma x_1(t)x_2(t) + b_3x_3(t)[x_1(t)x_2(t)] + b_4x_4 + \ldots b_px_p],$$

with $h_o(t)$ representing the underlying hazard of psychotherapeutic medicine use at age t for the reference category (i.e., all covariates = 0). The time-dependent covariates were represented by $x_1(t)$ = illicit drug use, $x_2(t)$ = psychiatric symptoms, $x_1(t)x_2(t)$ = interaction term for (symptoms) (illicit drug use), and $x_3(t)[x_1(t)x_2(t)]$ representing those for whom symptom onset preceded illicit drug use, with the term $x_3(t) = 1$ if symptom onset preceded illicit onset, and the fixed covariates were represented by $[x_4 \ldots x_p]$. The program BMDP 2L was used for fitting the models.[29]

Models 1–4 were generated for all respondents with

complete information on the fixed covariates (n = 1,537). The 25 widowed individuals were excluded from the analyses, since there were too few to generate stable estimates; most exclusions (142 of 179) were due to missing income data.

Since marital status, income, and help-seeking all were measured at the time of interview, the values for these variables prior to the onset of psychotherapeutic medicine use were not known. Therefore, no conclusions about the direction of their association with psychotherapeutic medicine use, if any, can be made. Despite this potential misspecification, these models offer a conservative test of the effect of illicit drug use on psychotherapeutic medicine use, since the covariates in question may be accounting inappropriately for variation due to illicit drug use.

Results

For the entire sample (n = 1,716), 554 (32 percent) of the respondents reported that they had used a psychotherapeutic medicine, 668 (39 percent) were positive for illicit drug use, and 785 (45.7 percent) had experienced psychiatric symptoms. Respondents were defined as positive for the predictor variables if they had used illicit drugs or experienced symptoms prior to the age of onset of psychotherapeutic medicine use or prior to the age at interview.

The age of onset of illicit drug use had a fairly limited range, with onset rarely occurring before age 10 or after age 29. The modal ages for initiation of illicit drug use were 16–19 years of age. Overall, the onset of psychotherapeutic medicine use was concentrated in the older ages of this sample. Instead of a relatively narrow period of initiation as was seen for illicit drug use, the onset of psychotherapeutic medicine use occurred in fairly steady proportions from ages 18–34.[30] The mean age of onset for illicit drug use was 19.35 years, and for psychotherapeutic medicine use 23.88 years.

Table 1 presents the results of the proportional hazards models which included illicit drug use and psychiatric symptoms, with adjustment for age, and for the fixed covariates race, sex, marital status, household income, and help-seeking. Model 1 showed that illicit drug use was associated with an increased risk of psychotherapeutic medicine use (rel. hazard = 2.65; 95% CI = 2.17, 3.21). That is, antecedent illicit drug use was associated with a risk of psychotherapeutic medicine use that was 2.65 times higher than the risk for individuals with no antecedent illicit drug use. In Model 2, the strength of illicit drug use as a predictor of psychotherapeutic medicine use was unchanged by adjustment for psychiatric symptoms. Thus, the presence in the model of a term for symptoms did not alter the relationship between illicit drug use and psychotherapeutic medicine use.

According to Model 3, illicit drug use was associated with an increased risk of psychotherapeutic medicine use whether symptoms had occurred (rel. hazard = 3.60) or had not occurred (rel. hazard = 3.10), with no significant interaction effect. Once again, illicit drug use was a predictor of psychotherapeutic medicine use and symptoms did little to alter this relationship.

Model 4 indicated that when both symptoms and illicit drug use occurred, respondents for whom symptoms preceded illicit drug use were more likely to initiate prescribed psychotherapeutic medicine use than persons for whom illicit drug use preceded symptoms (rel. hazards = 3.86 and 2.64, respectively). However, the confidence intervals were large and overlapped considerably (p = .063). In addition, those individuals with illicit drug use and no symptoms had a risk of psychotherapeutic medicine use similar to those experiencing either sequence of onset of symptoms and illicit drug use, suggesting that the presence of symptoms conferred little, if any, additional risk of psychotherapeutic medicine use over and above illicit drug use.

An additional version of Models 1 and 2 was generated that included onset of alcohol intoxication as a control variable. Onset of alcohol intoxication was defined as the age at which a respondent first reported becoming drunk, and was divided into three dummy variables that were not time-dependent: 1) onset from ages 3–15 years; 2) 16–20 years; and 3) >20 years, with the reference category defined as no onset of alcohol intoxication.

In Model 1, which was adjusted for onset of alcohol intoxication, there was little change in the strength of illicit drug use as a predictor (Table 2), as compared to the unadjusted Model 1 (Table 1). Similar findings were present for the alcohol-adjusted Model 2 (Table 2) as compared to the unadjusted Model 2 (Table 1).

Discussion

All of the models tested in this study showed an

association between illicit drug use and the later initiation of prescribed psychotherapeutic medication, even when controlling for initial occurrence of psychiatric symptoms. Symptoms did not change this relation. Model 4 showed that the risk of prescribed psychotherapeutic medicine use was elevated, whether illicit drug use preceded or followed onset of symptoms. Finaliy, adjustment of the models for the onset of alcohol intoxication did not alter these results.

Learned behavior[15] and sensation-seeking trait explanations[16] are both consistent with the finding that the association between illicit drug use and psychotherapeutic medicine use occurred independent of psychiatric symptoms, as drug use motivated by these explanations would take place without regard to distress state.[31] In terms of maturation and deviance,[13,14] the change in substances used, which may occur from adolescence to young adulthood, could be viewed as a move from behavior that is more deviant to a behavior that is more consistent with adult social roles.[32]

The results of this study are congruent with those of Yamaguchi and Kandel[6] in terms of the association between illicit drug use and psychotherapeutic medicine use, even though our study included a more diverse sample ranging in age from 18–44 years. Whether these results would hold elsewhere or at other times is a question of generalizability best addressed by replication and by greater attention to members of the population not typically interviewed in field surveys. As an example of how results might not generalize to other times, data were gathered in 1981, midway through the cocaine epidemic in the US. The possible impact of the epidemic on our findings is uncertain.

The key limitations to these findings relate to the retrospective character of the study data. For example, validity of self-reports of onset of psychological symptoms may be affected by many factors,[33,34] including severity of the symptoms, length of time since the symptoms were first experienced, and the number of episodes experienced over the lifetime. Similarly, the recency of use of the medicines and the amount of use,[35] as well as the indications for use (i.e., if nonpsychiatric) also could affect the accuracy of the findings.

In addition, the validity of the order in which drugs were used also is relevant. Evidence[36] supporting validity of self-reported order of drugs used comes from a series of repeated measures design surveys of drug use among high school seniors. The findings of these surveys consistently show that marijuana use precedes the use of other illicit substances. These surveys also corroborate findings of two studies[3,4] of sequencing of drug use which used retrospective lifetime reports. Nevertheless, some errors in this regard are possible, as are errors in ordering of onset of symptoms relative to drug use.

In conclusion, this study has shown a predictive association between illicit drug use and psychotherapeutic medicine use, independent of psychiatric symptoms. Future study of these relationships should include: 1) a design which would minimize memory/reporting errors, and 2) a more detailed examination of the etiologic mechanisms that might be responsible for this association.

Independence Foundation Grant to Establish Nursing Chairs at Nine Universities

Nine of the nation's nursing schools will benefit from a $9 million grant to endow an Independence Chair for Nursing at each institution. The award—made by the Independence Foundation of Philadelphia—is the largest foundation grant in the history of nursing education.

Robert A. Maes, president of the Independence Foundation, said that the interest from the grant should allow nursing programs to engage in long-term planning that will ensure the future of nursing education. "Unlike medical programs," he said, "nursing programs have not been richly endowed and consequently funds for planning have been scarce." The grant from the Independence Foundation will increase the number of nursing chairs in the United States from 38 to 47. Recipients of the grants are nursing schools at the following institutions: Case Western University, Emory University, Johns Hopkins University, New York University, Rush University, University of Pennsylvania, University of Rochester, Vanderbilt University, and Yale University.

The Independence Foundation, established in 1961 in Philadelphia, originated from the Donner Foundation of New York and, over the years, has largely given to secondary education. Since 1985, the Foundation has focused on the national nursing shortage and, two years later, began extensive scholarship funding of each of the nine schools involved in the new grant. In a further effort to draw attention to the national nursing shortage, the Foundation recently announced an increase in those scholarships, as well as the generous endowment of nine chairs for nursing in universities across the nation.

Increasing Rubella Seronegativity Despite a Compulsory School Law

TIMOTHY R. SCHUM, MD, DAVID B. NELSON, MD, MSc, MATTHEW A. DUMA, MD, AND GERALD V. SEDMAK, PhD

Abstract: To determine if lower rubella susceptibility persisted five to seven years after immunization legislation, we retrospectively reviewed the serologic status of 341 outpatients from 1985 to 1987 in an inner-city school age population. Seronegative rates increased significantly during the two-year study period from 4.2 to 24.5 percent (17 percent overall). (β = 6.8%, 95% CI = 3.3, 10.3).

Charts were reviewed for 57 of 58 seronegative and 114 seropositive controls. Estimates were then made to the population of 341 subjects. Those with documented rubella immunization had a seronegative rate of 13 percent compared to 19 percent if the immunization status was unknown. For patients who received care in our clinic for < two years, 32 percent were seronegative compared to 10 percent for those treated ≥2 years (odds ratio = 0.31, 95% CI = 0.16, 0.60). Among patients immunized in 1977 or 1978, 33 percent were seronegative compared to 7 percent immunized at other times (OR = 0.21, 95% CI = 0.07, 0.63).

Factors associated with increased rubella seronegativity include immunization in 1977 or 1978 and lack of continuity of care in our clinic. Much of the increase remains unexplained. (*Am J Public Health* 1990; 80:66–69.)

Introduction

In an attempt to prevent congenital rubella syndrome (CRS), rubella vaccination of all 15-month-olds is recommended.[1] This strategy has interrupted the six-nine year cycle of rubella epidemics and cases of rubella have decreased by 98 percent since the prevaccine era of 1969.[2] Outbreaks of rubella still occur in the adolescent/young adult age group, however,[3–5] leaving a serious potential for CRS.

The reported prevalence of rubella susceptible adolescents varies from 7 to 24 percent.[6–9] Nelson, *et al*, showed a dramatic decrease in rubella susceptibility in inner-city adolescent and preadolescent females from 22 percent to 5 percent when a mandatory school immunization law went into effect.[10]

The purpose of the present study was to determine whether this improved serologic status persisted, and what factors affect rubella immune status.

Methods

The Downtown Health Center is an inner-city clinic in Milwaukee, Wisconsin providing general pediatric care. The patient population is 75 percent Black and 85 percent Medicaid. All girls at or near the age of 10 years presenting for well child care, or for school or sports physicals, are routinely screened for rubella susceptibility. We reviewed the results of these tests from August 1985 through July 1987 and compared them with tests done in 1980 and 1981 (the same population with clinic name changed).

On the initial screen, we collected each patient's name, age, date, and result of her rubella titer. All rubella hemagglutination inhibition (HI) titers were measured by the City of Milwaukee virology laboratory using kaolin treatment of serums and one-to-three-day-old chick red blood cells. Titers of <1:10 were considered seronegative.[11]

In an effort to identify factors associated with increased seronegativity, we performed a case control study. From the population of 341 patients with known rubella titers, we did a detailed chart review on a subset of 171 patients—57 of 58 seronegative patients (one chart was unavailable) and 114 seropositive patients. Two seropositive controls were randomly selected for each seronegative case. Information collected from these charts included history and date of rubella immunization, type of immunization, clinic at which immunization was administered, type of health insurance, length of residence in Milwaukee, and current zip code. Seronegative rates for the population of 341 based on time periods could be calculated directly. However, population seronegative rates based on other parameters (history of immunization, duration of care in our institution, year immunized, and clinic of immunization) could not be calculated directly. Estimates of these rates were calculated using the overall incidence rates, odds ratios, and relative frequency of risk factors in the seropositive and seronegative groups.[12] This estimate takes into account the proportion of the subset exposed to a particular variable, e.g., year immunized, and then provides an estimate for the population of 341.

Patients were considered to have a positive history of immunization if a specific immunization date was recorded in their medical record. Immunizations given in our clinic also had the day and site of injection documented.

Differences in rates were measured using the Mantel-Haenszel estimate of the relative risk (odds ratio) with test-based confidence intervals.[13] To control for possible confounding, logistic regression was used.[14] Time trends were determined using a test for linear trend in proportions, a method similar to linear regression except each proportion is weighted by the sample size on which it is based.[15]

Results

Three hundred forty-one patients had their rubella serologic status determined during the two-year study period. Overall, 58 (17 percent) were seronegative. The seronegative rate was 5.8 percent in 1981[10] and 4.2 percent in 1985. However, from 1985 to 1987 there was a consistent increase in rubella susceptible girls to 24.5 percent (Table 1), β = 6.8% (95% CI = 3.3, 10.3).

Subsequent analyses refer to the estimates made on the population of 341 after chart review of the 171 cases. Seventy of 171 cases had documented immunization; 37 of these were immunized at another clinic; 27 were immunized in 1977 or 1978 (Table 2). Children without documented vaccination history were no more likely to be seronegative than children with a documented vaccination history, i.e., 19 percent vs 13

percent, respectively (Table 2). Patients immunized elsewhere had seronegative rates similar to those immunized at our clinic, 18 percent vs 16 percent, respectively. Children immunized at times other than 1977 or 1978 had lower seronegative rates than children immunized during 1977 and 1978, 7 percent vs 33 percent. Of the 171 patients, 117 were treated at our institution for greater than two years and showed a seronegative rate of 10 percent compared to a 32 percent rate for those treated here less than two years.

Of the 20 seronegative girls with documented immunization histories, 12 were immunized at 15 months or later, four between 12–14 months, and four at or near their first birthday.

Results from a logistic regression analysis are shown in Table 3. Only the following variables were simultaneously entered into the regression model: duration of treatment in our institution, clinic of vaccination, year vaccinated, and history of vaccination. Positive associations with rubella seropositivity were found for treatment in our clinic ≥2 years and for vaccination in years other than 1977–78.

The mean age for serosusceptible girls (11.9) was not significantly different from seroimmune girls (12.4). Type of immunization, e.g., combined measles-mumps-rubella, geographic location, insurance type, and length of time from immunization were not associated with rubella serologic status.

Variables	Odds Ratio	95% Confidence Intervals
Year vaccinated	0.17	0.06, 0.53
Clinic	0.75	0.24, 2.37
Time treated in our institution	0.27	0.15, 0.48
History of prior immunization	0.94	0.20, 7.80

Discussion

The sudden increase between 1985 and 1987 in seronegativity remains largely unexplained. But it is clear that improved rubella seropositivity associated with the school immunization law was not sustained in our population. The 17 percent prevalence of seronegativity in our 1985–87

population is similar to other reports,[7,8] in particular the 22 percent Nelson described prior to the institution of a statewide school immunization law.[10] Since July of 1987, the seronegative rate in our clinic has leveled off at 18 percent (54 of 300 from August 1, 1987 through January 31, 1989). The Milwaukee Health Department also noted an increase in rubella susceptibility in 1987, the highest level since 1979 (Table 4).

Several factors might explain increased seronegativity. One possible explanation would be failure to enforce the school immunization law. The school system, however, has reported no change in enforcement practices. Documentation of actual dates of immunization are and have been required for school entry. Another possible explanation is patient mobility and lack of continuity of care. The increased seronegativity in patients who have been attending our clinic for less than two years suggests this might have occurred. However, strict enforcement of the law should have identified these children.

Perhaps our 17 percent seroprevalence is biased or not generalizable because we could document immunization history in only 70 of 171 charts reviewed (41 percent). Seronegativity was 5.7 percent in Nelson's study even though they could document immunization history in only 46 percent of their patients,[10] making this an unlikely explanation.

Primary or secondary vaccine failure could explain the increased seronegativity, but our rate of 17 percent is higher than reported rates of 0–12 percent.[16–18,24,25] Secondary vaccine failure is unlikely as we found no association between seronegativity and time elapsed since immunization.

There was no evidence that the HI testing methodology explained the increased seronegativity. The HI test method, laboratory personnel, and titer cutoffs (1:8–1:10) have not changed. Newer testing methods are available and are more sensitive at detecting low antibody titers[21–23] but the standard for comparison still remains the HI test.

The current vaccine was licensed in 1979. We found significantly increased seronegativity for those immunized in 1977–78 but not before or after that time period. Perhaps there was a problem with particular lots of vaccine in those two years. Although problems with improper handling have been reported,[24,25] this is an unlikely explanation because seroprevalence rate was the same regardless of the clinic site.

Finally, the differences found might relate to selectively screening girls who are likely to be seronegative. This, however, is unlikely. The clinic clientele has not changed over the last 10 years. We see mostly Medicaid HMO (health maintenance organization) patients living in the inner-city and our referral patterns have not changed. All females age 8 or over presenting for well child care are eligible for screening. The vast majority are screened, although a few, known to be unvaccinated, will be immunized and not screened. Most patients are unaware of their rubella status and we do not require immunization records prior to screening. There is no reason to suspect this population was at increased risk for rubella seronegativity as most came to the clinic just for routine care rather than being referred for a specific problem.

Despite the increased seronegativity, we have not had sustained rubella transmission in Milwaukee since 1977 when a university-associated outbreak occurred. However, there was a mumps outbreak in the general population in 1987[26] and the possibility of a rubella outbreak exists. If the rate of serosusceptibility to rubella remains as it is, then a large number of women from this population may be entering their childbearing years, susceptible to rubella.

In summary, the dramatic impact of a mandatory school immunization law was not sustained seven years later. Rubella seroprevalence is now the same as it was prior to mandatory immunization laws although reported school enforcement has remained the same. Patients without a documented history of rubella immunization should be immunized as per current recommendations.[1] Females with prior rubella immunization should have rubella serology performed to assure immunity as documented history of rubella immunization did not guarantee seropositivity in our study.* The lack of continuity of care and rubella immunization during 1977–78 were significantly associated with increased seronegativity in our population. The sudden increase in seronegativity in just two years from 4 to 24 percent still remains largely unexplained but has leveled off at 17–18 percent. School enforcement of mandatory immunization laws is important but in Milwaukee is not sufficient to assure that girls approaching adolescence are protected against rubella.

TABLE 4—Rubella Serology from Specimens Submitted to the Milwaukee Health Department 1979–87

	Rubella Status		
	Seronegative	Seropositive	Total
Year	No. (%)	No. (%)	No.

Noise and Hearing Loss is Focus of Upcoming NIH Consensus Development Conference

Noise and hearing loss is the subject of an upcoming consensus development conference, to be held January 22-24, 1990 at the Masur Auditorium of the National Institutes of Health Clinical Center, Bethesda, Maryland. In the background material provided by NIH, it was noted that:

- Approximately 28 million individuals in the United States have impaired hearing;
- Exposure to occupational and recreational noise has, in many instances, caused irreversible damage to the inner ear;
- Sources of potentially damaging noise include high-volume music, recreational vehicles, airports, heavy traffic, lawn mowers, household appliances, chain saws, and power tools, to name a few;
- Hazardous levels of noise on the job are experienced daily by firefighters, military personnel, disc jockeys, construction workers, musicians, farmers, factory workers, taxicab/bus/truck drivers, and others.

The NIH conference will bring together specialists in hearing, physiology, and pathophysiology and other relevant fields. The purpose of the conference is to reach agreement on noise and hearing loss. Experts will present current scientific thinking about the diagnosis, management, and prevention of hearing loss, and concerned voluntary organizations will be invited to make statements. On the basis of the scientific evidence presented, the consensus panel will prepare a draft report and invite comments.

Key questions to be addressed include: 1) What is noise-related hearing loss? 2) What sounds can damage hearing? 3) What factors, including age, determine an individual's susceptibility to noise-related hearing loss? 4) What can be done to prevent noise-related hearing loss? 5) What are the directions for future research.

To register for the noise and hearing consensus conference or to obtain further details, contact: Dina Rice, Prospect Associates, Suite 500, 1801 Rockville Pike, Rockville, MD 20852. Telephone: (301) 468-6555.

Foreign-Born and US-Born Black Women: Differences in Health Behaviors and Birth Outcomes

HOWARD CABRAL, MPH, LISE E. FRIED, MSPH, SUZETTE LEVENSON, MPH, HORTENSIA AMARO, PHD, AND BARRY ZUCKERMAN, MD

Abstract: We studied health behaviors and birth outcome among 201 foreign-born and 616 US-born Black women receiving prenatal care at Boston City Hospital. Foreign-born women had better pre-pregnancy nutritional status and prenatal health behaviors, and their infants had greater intrauterine growth. Black women are not a homogeneous group; culture and ethnicity, in addition to other variables, must be considered in the study of their birth outcomes. (*Am J Public Health* 1990; 80:70–72.)

Introduction

In the United States, Black neonates are at high risk of low birthweight and increased perinatal mortality.[1–3] The rate of low birthweight among foreign-born Blacks is, however, two-thirds that of US-born Blacks.[4] The percentage of Black births in the US to mothers of foreign birth has increased in recent years. By 1986, this percentage had risen to 8 percent, an increase of 64 percent from 1976 and 39 percent from 1980, largely in urban areas of the northeast US.[5–7]

Differences in the rates of low birthweight among Blacks by foreign birth status may be related to lifestyle, since the health behaviors of those born outside of the US are different from those born in the US. For example, among Hispanics, those born outside of the US are less likely to smoke cigarettes, use illicit drugs, or receive late or no prenatal care than Hispanics born in the US, whose health behaviors more closely resemble those of US natives of other ethnic groups.[8–12,*]

The goal of this paper is to ascertain whether similar differences in health behaviors, and consequently birth outcomes, are present in a sample of 201 foreign-born and 816 US-born Black women receiving prenatal care at Boston City Hospital.

Methods

As part of a study of maternal health, psychosocial characteristics, health behaviors, and pregnancy outcome initiated in 1984, subjects were consecutively recruited in the prenatal clinics of Boston City Hospital. Interviews were conducted in English or Spanish at the time of prenatal registration and in the immediate postpartum period. Information on each participant's race and country of birth was obtained from closed-ended items on the initial interview. Substance use was assessed by self-report, except for marijuana and cocaine, which were also identified through urine assays. Infant assessments were conducted by pediatricians blind to the hypothesis of the analysis.

The 817 Black women presented here are a subsample of the total study sample of 1,226 women who delivered a liveborn, singelton infant and on whom complete data, including two interviews, a maternal medical record review, and an infant assessment, were available. A more detailed description of the study protocol and population has previously been published.[13]

Results

The demographic characteristics of the 817 Black women presented here are comparable to those of the low-income (47 percent with a monthly income of less than $500, 51 percent currently receiving Medicaid), inner-city prenatal population served by Boston City Hospital. Eighty-two percent of these women were unmarried, 15 percent were 18 years of age or younger, and 36 percent had received less than 12 years of education. Of the 616 US-born women, 7 percent were first generation Americans. Of the 201 foreign-born Black women, 72 percent were from Caribbean countries (40 percent from Haiti, 11 percent from Jamaica, 21 percent from other Caribbean countries), 17 percent from Africa, 8 percent from Cape Verde, and 3 percent from England. Country of origin was not significantly associated statistically with the dependent variables used in this analysis among women of foreign birth.

Foreign-born women were more likely to be older, married, better educated, to have better pre-pregnancy weight-for-height, and to have had nine or more visits for prenatal care than those born in the US (Table 1). The two groups of women were similar on parity, trimester of first prenatal visit, and pregnancy weight gain of less than 16 lbs. They were also less likely to smoke cigarettes, drink alcohol, or use marijuana, cocaine, or opiates during pregnancy (Table 2); in addition, they used fewer cigarettes and consumed less alcohol (data not shown).

TABLE 1—Comparison of Foreign-Born US-Born Black Women on Demographic and Selected Obstetric Factors

Factors	Foreign-Born (n = 201)	US-Born (n = 616)	% Difference	95% CI of Difference
	%	%		
Maternal Age				
18 years or younger	7	18	−11	(−6, −16)
Marital Status				
Married	33	12	21	(14, 28)
Maternal Education				
11th grade or less	22	40	−18	(−11, −25)
Monthly Household Income*				
$500 or less	44	48	−4	(−13, 5)
Pre-Pregnancy Weight-for-Height				
Less Than 90% of Ideal	6	13	−7	(−3, −11)
Primiparity	47	47	0	(−8, 8)
Trimester of First Prenatal Visit				
First or Second	87	85	2	(−3, 7)
Prenatal Care				
Less than nine visits	33	47	−14	(−6, −22)
Pregnancy Weight Gain				
Less than 16 lbs	12	16	−4	(−9, 1)

* of the 81% reporting an income

TABLE 2—Comparison of Foreign-Born US-Born Black Women on Substance Use Anytime During Pregnancy

Substance Used	Foreign-Born (n = 201)	US-Born (n = 616)	% Difference	95% CI of Difference
Cigarettes	12%	53%	−41	(−35, −47)
Alcohol	45%	64%	−19	(−11, −27)
Marijuana*	6%	39%	−33	(−28, −38)
Cocaine*	3%	24%	−21	(−17, −25)
Opiates**	1%	4%	−3	(−1, −5)
Other Drugs	1%	2%	−1	(−3, 1)

*Determined by positive self-report and or urine assay
**Heroin, Methadone

As seen in Table 3 infants of the foreign-born women were, at birth, heavier, longer, had larger head circumferences, and had longer durations of gestation than did infants of the US-born women. Foreign-born Black women in this sample were also less likely to have given birth to a low birthweight (≤2500 grams) infant (odds ratio = 0.59, 95% CI = 0.33, 1.03) or a premature (<37 weeks gestation) infant (odds ratio = 0.46, 95% CI = 0.22, 0.94) than those born in the US.

After controlling for the effects of gestational age, weight gain during pregnancy, pre-pregnancy weight-for-height, marital status, maternal age, level of education, the number of visits made for prenatal care, and the use of cigarettes, alcohol, marijuana and cocaine during pregnancy, infants born to foreign-born Black women remained heavier, longer, and larger in head circumference at birth than infants born to US-born Black women (Table 3). Duration of gestation was not different between infants of foreign-born Black women and infants of mothers born in the US. The adjusted odds of having a low birthweight infant or a premature infant remained decreased for foreign-born Black women as opposed to Black women born in the US (odds ratio, low birthweight = 0.81, 95% CI = 0.42, 1.53; odds ratio, prematurity = 0.54, 95% CI = 0.24, 1.18).

TABLE 3—Differences in Fetal Growth Measured at Birth between Infants of Foreign (N = 201) and US-Born (N = 616) Black Women

	Foreign-Born vs US-Born		Foreign-Born vs US-Born	
	Unadjusted Difference	95% CI of Difference	Adjusted Difference	95% CI of Difference
Birthweight	272 g	(174, 369)	135 g	(51, 218)
Length	1.3 cm	(0.9, 1.8)	0.7 cm	(0.2, 1.1)
Head Circumference	0.8 cm	(0.5, 1.2)	0.4 cm	(0.1, 0.7)
Gestational Age	0.4 wk	(0.01, 0.7)	0.3 wk	(−0.1, 0.7)

Discussion

The infants of foreign-born Black women experienced greater intrauterine growth than those of Black women born in the US, even after accounting for many of the factors known or suspected to influence fetal growth. Why such a difference remained deserves more in-depth study than these data can provide.

The following limitations should also be considered when interpreting these findings:

- First, although the percentage of births to foreign-born Black mothers in these data virtually matches that of the entire northeast US (26 percent) in 1986,[7] it is possible that the characteristics of the women studied here are unique to the Black population who use Boston City Hospital as their primary source of prenatal care.
- Second, foreign birth status is an approximation of the cultural characteristics of these women and does not necessarily reflect the heterogeneity of either the US or foreign-born Black women in this regard.
- Third, the exclusion of non-English or non-Spanish-speaking women, who may have been less acculturated to US norms than those who participated, may have affected these findings.

These data illustrate some important differences in prenatal risk and birth outcome by foreign birth status within the prenatal population of Black women at Boston City Hospital. They suggest that low-income Black women are not a homogeneous group in terms of prenatal risk and birth outcome, and highlight the importance of considering ethnicity as indicated by place of birth, in addition to race, as a demographic factor in the study of the relationship of maternal prenatal health behaviors and birth outcomes.

ACKNOWLEDGMENTS

This paper is a revised version of a presentation made at the 116th annual meeting of the American Public Health Association, Boston, Massachusetts, November 13–17, 1988. The authors would like to acknowledge Gabrielle Lopez, Elva Perez Trevino, Claudia Caicedo, Julie Skoler, and Isolde Goernemann for conducting the interviews; Rose Dobosz for the coding of the data and subject tracking; Julie Johnson and Michael Winter for data processing; and Lee Strunin, PhD, Tim Heeren, PhD, and Herb Kayne, PhD, for their reviews of the manuscript.

Supported by National Institute on Drug Abuse (R01DA03509) and Bureau of Health Care Delivery and Assistance, Maternal and Child Health Branch (MCJ-009094).

Some Sources of Error in the Coding of Birth Weight

ANDREW J. BRUNSKILL

Abstract: Three types of error in coding birth weight to computer tapes are described: 1) confusion of ounces with pounds, 2) mistaken reading of one pound as eleven pounds, and 3) errors in placement of the decimal. All will allocate low birth weight infants to high birth weight categories. Examination of the reported gestational age of the infant or of the reported cause of death may allow these errors to be detected. (*Am J Public Health* 1990; 80:72–73.)

Introduction

There is increasing use of computerized birth certificate records in pediatric epidemiology. Such records may contain both systematic and random errors. David described sources of systematic error in the recording of birth weight and gestational age in North Carolina birth certificates.[1] In that study, it was suggested that when birth weight was abnormally large for gestational age, gestational age was most likely to be inaccurate. However, original birth certificates were not actually compared to the birth tapes for accuracy of transcription. Although the need for careful editing of data is emphasized by experienced researchers, the nature and the effects of errors which occur in coding seem to have received less emphasis.

Methods

This analysis is based on a partial review of the cases present in a state birth tape of 1984–85 data. For those infants who had died within the first year of life, linked death certificates were also available. All White infants with birth weights of 4.5 kgs or greater ("macrosomic") were sampled and a corresponding random sample in an approximately 2:1 ratio of infants with birth weights 2.5–4.0 kgs. This selection, which related to the primary aims of a project on macrosomia, yielded 5,399 macrosomic and 10,250 control infants. Within these samples, the records of all those infants who had died in the first year of life were reviewed and the birth weight reported on the birth certificate compared with the birth weight reported on the computer tape. Additionally, 34 birth certificates of those infants with the highest birth weights who had not died were reviewed to bring the total number of birth certificates reviewed to 120.

Results

Within the high birth weight group, 39 infants were reported to have died within the first year of life. However, 18 cases of miscoded birth weight were detected in this group, leaving only 21 infants whose birth weights were confirmed as being high. Within the normal control group, 47 infants were reported to have died within the first year of life. The birth weights of all these infants were confirmed as correctly coded. All of the additional high birth weight infants who had survived the first year of life and whose certificates were checked had correctly coded birth certificates.

Three types of errors appeared to be responsible for the miscoding:

- One type of error is the confusion of ounces with pounds. Examples include 12 oz being coded as 5,443 grams (12 lbs), and 14 oz being coded as 14 lbs. This error occurred in nine of the 18 cases of detected coding error.
- The second type of error consisted of mistaken reading of birth weights of one pound or more as eleven pounds. The ease with which one pound can be misread as eleven pounds can be understood by considering the abbreviation used for one pound (1 lb) where the lower case letter "l" is mistaken for a second digit one "1." This is illustrated in Figure 1 which consists of a photocopy of the relevant part of the six birth certificates in which all six birth certificate weights were coded as eleven pounds. In fact, only the infant whose birth certificate is coded as "e" had a true weight of eleven pounds. This error occurred six times in the series.
- The third set of errors occurs when a decimal is wrongly placed in metric values. This includes cases such as 510 grams being mistakenly coded as 5100

Infant Formula Promotion and the Health Sector in the Philippines

BARRY M. POPKIN, PHD, MARIA ERLINDA FERNANDEZ, MS, AND JOSEFINE L. AVILA, MS

Abstract: We use data collected in 1984, 1986, and 1988 from public and private health facilities in the Metropolitan Cebu area of the Philippines to assess effects of World Health Organization and Government of the Philippines Codes of Marketing of Breast Milk Substitutes on distribution of formula supplies. Distribution of free and low-cost infant formula declined drastically between 1986 and 1988. Industry compliance was almost complete. (*Am J Public Health* 1990; 80:74–75.)

Introduction

After nearly a decade of controversy on the role of infant formula promotion in changes in Third World breast-feeding behavior, the World Health Assembly adopted the International Code of Marketing of Breast Milk Substitutes on May 21, 1981. Most troublesome among these provisions was Article 6, paragraph 6, stating that "[d]onations or low-price sales to institutions or organizations of supplies of infant formula or other products within the scope of this Code, whether for use in the institutions or for distribution outside them, may be made. Such supplies should only be used for, or distributed to, infants who have to be fed on breast milk substitutes."[1]

The World Health Organization (WHO) Guidelines issued on April 10, 1986, defined "infants who have to be fed on breast milk substitutes" as those who have rare metabolic disorders, cannot suck, or are motherless through death or abandonment as well as those whose mothers have decided not to breast-feed, fully or partially, for whatever reason.[2] The World Health Assembly passed a resolution on May 16, 1986 urging governments to take action "to ensure that the small amounts of breast-milk substitutes needed for the minority of infants who require them in maternity wards and hospitals are made available through the normal procurement channels and not through free or subsidized supplies."[3]

On December 22, 1986, the Philippine Government passed its own code of infant food marketing (the GOP code),[4] banning the distribution of free and subsidized formula supplies to hospitals.

WHO in 1988 affirmed that the International Code, which permits free or subsidized supplies of infant formula for infants who have to be fed on breast milk substitutes, had not been modified by the 1986 World Health Assembly Resolution.[5,6]

While the International Code acknowledges a legitimate market for infant formula that includes mothers who cannot breast-feed or choose to bottle-feed, the National Code for Marketing of Breast Milk Substitutes of the Government of the Philippines is silent on the issue of procurement and forbids infant food manufacturers and distributors from giving free supplies to the general public, hospitals, and other health facilities and medical personnel except on request by, or with the approval of, the Department of Health (DOH). Approval by the DOH is given only for catastrophic occurrences such as floods or famine. Violators of the GOP Code face fines or imprisonment. Omission of any reference to procurement in the GOP code raises questions on how to obtain formula for infants unable to breast-feed and/or whose mothers are unwilling or unable to suckle them. We analyzed existing data to assess the effect of these different codes on hospital practices.

Methods

Between 1984 and 1988, as part of a larger study, we surveyed health facilities serving the Philippines' second largest metropolitan area (Cebu City) three times. During this period, the major infant food companies serving this market (American Home Products, Bristol-Myers, Nestlé, and Abbott) had accepted the WHO Code.

We collected data from 73 (1984), 78 (1986), and 72 (1988) Metropolitan Cebu health facilities, all providing prenatal and obstetrical care. These facilities include all public and private hospitals and a representative sample of clinics and health centers. Approximately 70 percent of these facilities are public (government) institutions; about one-fifth of the public facilities and three-fourths of the private facilities have on-site obstetrical services; the remainder provide home-delivery assistance.

We obtained information on whether facilities had received any infant formula, other milk, or food supplies in the three months preceding each survey from manufacturers of those products; the brand name and source of each sample received; how the facilities had used infant formula supplies; and their policies toward industry representatives. The 1988 survey asked additional questions on procurement practices particularly for higher risk infants such as premature babies confined in special care nurseries.

Results

The proportions of facilities receiving as manufacturers' gifts any kind of milk remained basically unchanged between 1984 and 1986 but fell in the following two years (Table 1): infant formula distribution declined by 95 percent, while the proportion of facilities with formula for older infants increased by 80 percent in the same period. These foods intended for use as the liquid part of the weaning diet are not covered by the WHO or GOP codes.* The same applies to any weaning food.

Before passage of the GOP code, public facilities with on-site delivery were most likely to receive free formula (Table 2). All on-site delivery facilities show an increase in

*Editor's Note: "Follow-up" formulas have not been marketed successfully in the United States. A policy statement of the American Academy of Pediatrics, "Follow-up or Weaning Formulas," appears in the February 1989 issue of AAP News.

TABLE 1—Percentage of Facilities Receiving Any Infant Food as Gifts by Type

Type of Food	1984	1986	1988
Infant formula	57.5	52.6	2.8
Follow-up formula	11.0	15.4	27.8

distribution of formula supplies between 1984 and 1986 by all manufacturers. In the 1988 survey we find only one manufacturer still distributing free formula supplies. Recipients were two private health facilities with on-site delivery which had received a soy-based preparation.

In 1984 and 1986, over half the total sample of facilities had distributed free samples to mothers; in 1988, only 3 percent still did so (data not shown).

The proportions of facilities allowing representatives to visit their patients rose from 30 percent to 40 percent from 1984 to 1986. In 1988, only 2.6 percent of the facilities allowed them to do so. Moreover, only seven of 72 facilities in Metropolitan Cebu still supplied clients' names to industry representatives—a marked decrease from previous years.

The 1988 survey found that seven private facilities sold infant formula in their own hospital pharmacies, an increase from two in 1984 and five in 1986. Bottle-feeding mothers who deliver in these private facilities have a choice of purchasing formula from these pharmacies or from outside sources. Mothers delivering in public hospitals have to buy formula from outside retail outlets if they need or want to bottle-feed their newborns.

Discussion

The trends shown over these three surveys suggest that the WHO International Code of 1981 had little direct influence in reducing the level of infant formula donations to hospitals which the Code did not prohibit.

TABLE 2—Percentage of Facilities Receiving Free Infant Formula Supplies from Specific Industry Sources by Facility Type and Year of Survey[a]

	1984		1986		1988	
Facility Type	%	(N)	%	(N)	%	(N)
Public facility						
With on-site delivery	85.7	(7)	100.0	(7)	0.0	(6)
Without on-site delivery	54.4	(46)	38.0	(50)	0.0	(46)
Private facility						
With on-site delivery	78.6	(14)	93.3	(15)	13.3[b]	(14)
Without on-site delivery	0.0	(6)	16.7	(6)	0.0	(6)

[a]Formula supplies were received within a three-month period preceding each survey.
[b]Soy-based formula only.

While committing itself to eliminating indiscriminate distribution of infant formula supplies, industry took the position that the responsibility of providing directives to health care facilities and manufacturers on infant formula promotion rests with national governments. We observed significant decreases in such activities in 1988 which may be attributable to restrictions and penalties of the National Code passed by the Philippine Government late in 1986.

Whether the changes in the distribution of free supplies observed in the 1988 survey will lead to an increase in breast-feeding among Filipino mothers and an improvement in infant health and development is still unknown. What is apparent is that present policies and practices are designed to make it inconvenient and difficult for mothers to bottle-feed in hospitals.

Finally, it is important to note that this study does not imply that the WHO Code has been of no value. The WHO Code has served as the basis for the development of country codes and has centered extensive publicity on the need to use legislation as one means of promoting breast-feeding. The GOP Code is noteworthy in being one of the first to implement the purpose of the 1986 WHO resolution.

A Randomized Evaluation of Smoking Cessation Interventions for Pregnant Women at a WIC Clinic

JEFFREY P. MAYER, PHD, BARBARA HAWKINS, MA, AND RANDALL TODD, DHSC, MPH

Abstract: Pregnant smokers attending a local health department WIC clinic were randomly assigned to one of two self-help smoking cessation programs or usual care. The multiple component program resulted in larger quit rates than usual care during the last month of pregnancy (11 percent vs 3 percent) and postpartum (7 percent vs 0 percent). Achieving quit rates in WIC similar to those in studies conducted at prenatal care settings, suggests that smoking cessation programs for low-income pregnant WIC clients are feasible. (*Am J Public Health* 1990; 80:76–78.)

Introduction

Estimates suggest that 32 percent of all women of child-bearing age smoke with only 21 percent quitting during pregnancy.[1] Evaluations of self-help cessation programs have demonstrated some success with pregnant women receiving prenatal care at an HMO (health maintenance organization),[2] private practices,[3] hospital clinics,[4*] and local health departments.[5]

WIC (the Special Supplemental Food Program for Women, Infants, and Children) is an unexplored setting for smoking cessation research. Analyses of matched WIC-birth certificate data for Missouri in 1982 indicated that 45 percent of pregnant women WIC participants were smokers,[**] 50 percent higher than the 30 percent rate observed among all Missouri women that year. Data on 127,512 pregnant women enrolled in several state WIC programs from 1979 through 1985 suggested that smokers were 2.5 times more likely to deliver a low birthweight infant, and that very few participants stopped smoking following their enrollment in WIC.[***]

The present investigation is a randomized trial of a self-help smoking cessation program implemented at a local health department WIC clinic

Method

The study was conducted from August 1985 to August 1986 at the Kent County Health Department in Grand Rapids, Michigan. A brief structured interview was used to characterize an incoming pregnant women as a current smoker (at least one cigarette per day), a nonsmoker, or a former smoker. Current smokers were asked to participate in the study and to complete an informed consent statement and a pretest. Following informed consent, participants were randomly assigned to one of three groups.

The usual care (UC) group received printed information about the risks of smoking during pregnancy and completed the clinic in the traditional manner.

The multiple component (MC) group received a 20-minute one-to-one counseling session which included both risk information and behavior change components. The risk information component employed the *Because I Love My Baby* materials developed by the American Lung Association. These materials included a "flip chart" used by the health educator in presenting the information and a printed brochure given to clients to take home.

The behavior change component of the MC intervention employed a self-help manual adapted from Windsor, *et al*,[5] and from the American Lung Association's *Freedom From Smoking* program. Behavioral contracting and self-monitoring were the primary strategies. An individual behavioral contract was developed during the session which specified a quit date and selection of some significant other as a co-signer. Self-monitoring included charts for recording daily smoking behavior, and the development of an individualized plan of action for breaking recorded behavioral chains.

The risk information (RI) intervention was a face-to-face session of about 10 minutes duration. The health educator used the same "flip chart" as the MC group and provided the factual brochures, but did not present behavior change counseling, or furnish the self-help manual.

During the postpartum WIC visit, the posttest was completed, which included questions about smoking during the final month of pregnancy as well as postpartum. The postpartum self-reports, on average, occurred 4.7 weeks following birth of the infant, a relatively short period. Saliva samples (N = 66) were collected from the last one-third of the participants. The correlation between the saliva thiocyanate and self-report measures (r = .25) was similar to correlations found in more extensive analyses with larger samples that showed excellent sensitivity and specificity.[6,7] Saliva samples were equally distributed across groups (28 percent of MC participants, 30 percent of RI participants, and 32 percent of UC participants). Resource constraints did not allow collection of more complete data.

Demographic and health service data were abstracted from WIC program records for study participants and for the women who refused to participate. Agreement rates between different coders, and between the WIC record and prenatal care medical record, for a 30 percent random sample, were 99.2 percent and 87.9 percent, respectively.

Results

Two hundred and seventy-one of 641 pregnant women entering the clinic were identified as current smokers (42 percent); 219 volunteered to participate in the study (81 percent). Of these 219, posttest data were collected from 186 (15 percent attrition rate) (about one-fourth actually refused to complete the posttest; three-fourths either moved from the community, left the

WIC program, or miscarried). Those lost to follow-up were treated as continuing smokers in the following analyses.

Differences between study participants and refusals on variables available from the WIC record were relatively minor for important variables as were study group differences (Table 1).

Table 2 presents the quit proportions and differences by treatment group for both follow-up periods. The MC group quit rate was higher than the UC group at both post time periods. While all UC participants had returned to smoking postpartum, some proportion of the participants in the MC and RI groups remained smoke free.

Discussion

The 42 percent smoking rate among pregnant women entering the WIC clinic was similar to the estimates of Land and Stockbauer,** and was indicative of the important need for smoking intervention at WIC clinics. The quit rate for the MC group (11 percent) was just under that found at prenatal care settings serving low-income women. Both Windsor, *et al*,[5] and Secker-Walker *et al*,* in studies conducted at low-income public maternity clinics, reported quit rates of 14 percent.

Although limitations of the present formative evaluation study include small sample size, and lack of complete biochemical verification, the findings have preliminary implications for extending health education services to pregnant smokers visiting WIC clinics. The high level of program acceptance among our WIC participants (81 percent) is impressive. Although prenatal care settings see pregnant women more regularly, offering the possibility of multiple health education contacts (and potentially improved quit rates), the WIC program, with broader eligibility than typically found at public prenatal care clinics, would seem to offer greater opportunity to reach a larger share of low-income women. Additionally, WIC clinics offer the advantage of a centralized site where health educators and public health nurses can be made available to provide one-to-one counselings.

Eight-Year Follow-Up Results of an Adolescent Smoking Prevention Program: The North Karelia Youth Project

ERKKI VARTIAINEN, MD, PHD, UNTO FALLONEN, PHD, ALFRED L. MCALISTER, PHD, AND PEKKA PUSKA, MD, MPOLSCI

Abstract: In the North Karelia Youth Program five to 10 classroom sessions over two years taught skills to resist pressures to start smoking to 13 to 15 year old students. Compared to students from comparison schools, the treatment groups reported less smoking immediately after the intervention and in a four-year follow-up survey. At the eight-year follow-up, there was consistent evidence of possible preventive effects only among those who had been nonsmokers when the program began. (*Am J Public Health* 1990; 80:78–79.)

Introduction

From 1978 to 1980, a study to demonstrate methods for reducing cardiovascular risk factors in 13-year-old students was carried out in the province of North Karelia, Finland. One of the main aims was to prevent the onset of smoking.[1] Although many studies of the effectiveness of persuasive and behavioral approaches to smoking prevention have been carried out,[2] long-term follow-up is rare.[3,4] Details of the methods and the outcome of the intervention immediately after the program[1], after half a year[5], and two years after the program[6] are reported elsewhere. This brief report describes the follow-up results eight years after the program ended.

Methods

In brief, three pairs of matched schools were chosen for the program. In two "direct" program schools, 10 sessions were carried out during a two-year period from 1978 to 1980 by the project health educator and trained peer leaders. In two "county-wide" program schools, five behavioral sessions were to be carried out by health education teachers at the schools who were trained as part of an effort to disseminate new curricula throughout North Karelia. Two schools were chosen for controls from another province in eastern Finland. In each matched pair, one school was chosen from the capital of the county and the other from a rural village. The program began in 1978 among the seventh graders and finished with the ninth grade in autumn 1980. During the persuasive-behavioral sessions, students were taught about

social pressures that may lead to smoking (peer, adults, and mass media) and were trained to deal with such pressures through role playing and other active learning techniques. Older peer leaders assisted in implementing the program at school. The short-term and long-term health hazards were also discussed during the program. At the pretest, there were 897 students in the seventh grade in the three pairs of matched schools. At the posttest, the participation rate varied from 92–97 percent, in the eight-year follow-up from 72–79 percent. In all the surveys, the smoking habits of students were asked by the following question: Do you smoke now? Multiple choice responses: 1) Not at all; 2) Less than once a month; 3) One to two times a month; 4) One–two times a week; 5) Daily.

Results

When the youth were in the seventh grade, the proportion who reported smoking at least once a month varied in schools from 4–9 percent. Immediately after the program, there were one-third fewer smokers in both types of intervention schools compared to control schools. One half year and two years later, the difference was about the same, although smoking increased during the follow-up. In 1986, six years after the program had terminated, an increase in smoking between ages 16 and 21 was seen (Figure 1). The differences between the direct program (38 percent smokers) and reference schools (42 percent smokers) were minimal, while the differences between the county-wide program and control schools were more impressive (31 vs 42 percent). When only those students who reported they were nonsmokers in the pretest were included in the analyses, the proportion of nonsmokers was lower in both the direct and teacher-led schools than in the controls at the eight-year follow-up (Table 1). If attrition is taken into account by assuming all dropouts to be smokers, smoking rates in the two treatment groups are more similar (48–49 percent) but they remain

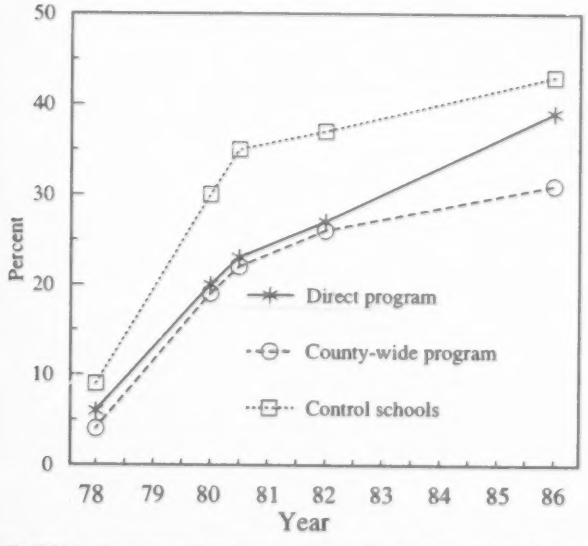

FIGURE 1—Proportion of Students Who Reported Smoking at least Once a Month in Different Surveys

CI = confidence interval

lower than the rate of smoking in the campaign group (59 percent). This adjustment probably overestimates smoking prevalence.

Discussion

The interpretation of these results is complicated by several factors. Implementation evaluation of the project indicated that students at the urban school in the county-wide condition received only one or two anti-smoking sessions as part of the regular health education curriculum. The urban junior high school in the control condition shared its school yard with a senior high school whose students were allowed to smoke in the school yard. The primary difference that was observed, lower smoking rates, could be attributed to the overall community program in North Karelia rather than the specific programs that were carried out in the study schools. Given these qualifications, we cannot conclude from this study that preventive programs at school have long-term effects on smoking. On the other hand, our findings are consistent with the hypothesis that community and school programs can influence youthful nonsmokers to avoid tobacco.

The Effects of Detoxification of Domestic Gas on Suicide in the United States

DAVID LESTER, PHD

Abstract: As domestic gas was detoxified in the United States, the rate of suicide by domestic gas decreased. During this time period (1950–60), there was a parallel increase in the per capita ownership of cars and an accompanying increase in the rate of suicide by motor vehicle exhaust. However, displacement of suicide method from domestic gas to car exhaust occurred only for males and not for females. (*Am J Public Health* 1990; 80:80–81.)

Introduction

It has been argued that the detoxification of domestic gas in England and Wales in the 1960s and early 1970s was responsible not only for a drop in the rate of suicide by domestic gas, but also for a drop of about one-third in the overall suicide rate.[1,2]

However, it has also been noted that detoxification of domestic gas in Scotland and The Netherlands was not accompanied by a decrease in the overall suicide rate. Clarke and Mayhew[3] have suggested that this reflected a rising suicide rate in Scotland and The Netherlands at the time of detoxification which masked any reduction made possible by the detoxification of domestic gas.

Lester[4] has argued that, in the states of the USA where the availability of firearms is reduced by strict gun control laws, there is an accompanying reduction not only in the rate of suicide by firearms, but also in the overall suicide rate. Rich and Young[5] have shown that in Toronto people switched from using firearms to jumping in front of subway trains, leaving the suicide rate unchanged.

Domestic gas in the United States contained carbon monoxide in the early part of this century. The carbon monoxide content was reduced gradually during the 1940s and 1950s as gas companies switched to natural gas. The present paper examines the relation of the detoxification of domestic gas with rate of suicide.

Address reprint requests to David Lester, PhD, Psychology Program, Richard Stockton State College, Pomona, NJ 08240. This paper, submitted to the Journal January 30, 1989, was revised and accepted for publication May 17, 1989.

During this same period, the per capita ownership of cars increased in the USA. The per capita ownership of cars in the states of America is positively associated with the use of car exhaust for suicide.[6] The present paper, therefore, also explored whether people used car exhaust rather than domestic gas as a suicide method as the relative availability of these two methods for suicide changed.

Method

Data on the rates of suicide by domestic gas and motor vehicle exhaust were obtained from the annual volumes, *Vital Statistics of the United States*, published by the National Center for Health Statistics. Data on the percentage of customers receiving natural gas were obtained from the annual volume *Statistical Abstract of the United States*, published by the Bureau of the Census. Data on the number of cars per capita each year were obtained from *Historical Statistics of the United States from Colonial Times to 1970* published by the Bureau of the Census.

Data were obtained each year from 1946, the first year for which data on domestic gas customers could be obtained using a consistent set of categories, to 1970, by which time almost all domestic gas customers were receiving natural gas. Suicide by natural gas is possible, but since natural gas is less toxic, suicide is by the exclusion of air containing oxygen and is less apt to occur.

Results

Table 1 shows that the percentage of domestic gas customers receiving natural gas increased from 1950 to 1970 (regression coefficient = 22.75, standard error = 1.86), as did the number of cars per capita (regression coefficient = 8.90, standard error = 0.22). The accidental death rate from domestic gas was strongly and positively related to the percentage of customers receiving the toxic manufactured or mixed gas and with the rate of suicide by domestic gas.*

The rate of suicide by domestic gas decreased over the years (regression coefficient = −34.70, standard error = 4.12), while the rate of suicide by motor vehicle exhaust increased (regression coefficient = 29.45, standard error = 2.52). The sum of these two suicide rates remained constant

*Complete tables of data are available on request to author.

TABLE 2—Changes in the Suicide Rates 1950–70, by Method for Men and Women

	Suicide Rates by Men				Suicide Rates by Women			
	Motor Vehicle Exhaust	Domestic Gas	Total Gas	Other Methods	Motor Vehicle Exhaust	Domestic Gas	Total Gas	Other Methods
1950	1.09	0.85	1.94	15.75	0.12	0.61	0.73	4.32
1955	1.29	0.23	1.52	14.33	0.21	0.16	0.37	4.18
1960	1.55	0.13	1.68	14.78	0.29	0.07	0.36	4.59
1965	1.74	0.11	1.85	14.69	0.51	0.06	0.57	6.04
1970	1.48	0.03	1.51	15.30	0.61	0.01	0.62	5.95

during this period (regression coefficient = −3.81, standard error 6.67). The rates of suicide by domestic and motor vehicle gas were negatively related (r = −0.94). The total suicide rate during this period did not change systematically (regression coefficient = 1.84, standard error = 15.56).

The data were examined separately for men and women (Table 2). The use of domestic gas for suicide by men declined from 1950 to 1970 while the use of car exhaust increased. The use of both methods varied greatly from year to year, but the data suggest a slight decrease over the period. For women, the results are similar, except that the data suggest a drop in the use of domestic gas and car exhaust from 1950 to 1960 followed by a rise from 1960 to 1970.

Discussion

It has often been argued that removal of one lethal method for suicide will simply cause would-be suicides to turn to alternative methods.[7] The present results indicate that as domestic gas was detoxified and as per capita ownership of cars increased, fewer people used domestic gas for suicide while more used motor vehicle gas for suicide.

The situation is considerably more complicated, of course. During this period (1950 to 1970), the availability and use of firearms for suicide was increasing,[8] as perhaps was the availability of lethal medications such as antidepressants. Thus, as domestic gas became less toxic, several other methods for suicide became more available. This, together with the lesser use initially of domestic gas for suicide in the US as compared to England and Wales, is perhaps why detoxification of domestic gas in the US had little impact on the overall suicide rate, while in England and Wales detoxification of domestic gas was accompanied by a one-third reduction in the overall suicide rate.[7]

The data are not clear on whether switching occurred from domestic gas to car exhaust as the relative availabilities of these methods changed. A case could be made for or against switching, depending upon which time period (1950–60 or 1960–70) and which sex is examined. Two important questions for future research are: "Which people will switch methods for suicide if one is made less available?" and "To which methods will people switch if one method is made less available for suicide?"

ACKNOWLEDGMENT

I should like to thank Dr. Ronald Clarke for advice in the preparation of this paper.

NIA Funds Three New Alzheimer's Disease Research Centers

The National Institute of Aging (NIA) has announced funding of three new Alzheimer's Disease Research Centers (ADRCs), with $2.3 million for the first year of operation and a total of $11 million over the next five years. This brings to 15 the number of Alzheimer's centers funded by the NIA. The purpose of the ADRC program is to enhance research on Alzheimer's disease by providing the resources and environment for collaborative, multidisciplinary studies. Each center will serve as the site for new and expanded studies of the basic, clinical and behavioral aspects of Alzheimer's disease. In addition to their research mandate, the centers train scientists and health care professionals and offer consultation and education to Alzheimer patients and their families.

The three new centers are located at Baylor College of Medicine, Houston, Texas; Columbia University, New York City; and the University of Michigan, Ann Arbor.

The other 12 NIA-funded centers are located at: Duke University, Durham, NC; Harvard Medical School/Massachusetts General Hospital, Boston, MA; Johns Hopkins Medical Institutions, Baltimore, MD; Mt. Sinai School of Medicine/Bronx VA Medical Center, New York; University of California-San Diego, La Jolla, CA; University of Kentucky, Lexington, KY; University of Pittsburgh, Pittsburgh, PA; University of Southern California, Los Angeles; Case Western Reserve University, Cleveland, OH; University of Washington, Seattle, WA; Washington University, St. Louis, MO; and University of Texas, Southwestern Medical Center, Dallas, TX.

Variables Influencing Condom Use among Intravenous Drug Users

STEPHEN MAGURA, PHD, JANET L. SHAPIRO, MA, QUDSIA SIDDIQI, PHD, AND DOUGLAS S. LIPTON, PHD

Abstract: Correlates of condom use were identified using cross-sectional data from a convenience sample of 211 sexually active intravenous drug users enrolled in methadone maintenance in New York City. Sixty-eight percent did not use condoms at all in the previous month and only 11 percent used condoms every time. Nineteen percent were planning on conception, only 20 percent of whom had been tested for human immunodeficiency virus (HIV) antibody (all seronegative). Multiple logistic regression analysis indicated that condom use was independently associated with greater personal acceptance of condoms, greater partner receptivity to sexual protection, and recent entry to methadone treatment. *Am J Public Health* 1990; 80:82–84.)

Introduction

Thirty percent of adult AIDS (acquired immunodeficiency syndrome) cases diagnosed in the United States during 1988 involved intravenous drug users (IVDUs).[1] In New York City, at least 50 percent of IVDUs are already HIV (human immunodeficiency virus) seropositive.[2,3] There has been extensive public health focus on reducing needle-sharing and other drug-use-related HIV transmission risks within the IVDU population.[4] However, sexual contact is an important secondary means of HIV transmission among IVDUs and is the main route of HIV transmission to the general heterosexual population.[5,6] Heterosexual contact accounted for 5 percent of US adult AIDS cases diagnosed during 1988.[1] Infected IVDU women are also the primary source of perinatal HIV transmission.[7]

Condoms are an accepted measure to prevent the sexual transmission of HIV; they also can be a useful although not fully effective birth control method for seropositive women.[8–10] One recent study found that only 13 percent of IVDUs used condoms (usually inconsistently) and that 65 percent of their sexual contacts were with non-IVDUs; the sample was drawn from a treatment population with 57 percent HIV seroprevalence.[11] Overall there has been little or no change in sexual practices in response to the AIDS threat either among IVDUs[12–14] or the general heterosexual population.[6] We present a quantitative analysis of the factors influencing IVDUs' decisions about condom use.

Methods

The study sample is 289 IVDUs enrolled in methadone maintenance who had volunteered for an AIDS prevention demonstration/research project at three New York City clinics. Because participants were self-selected, they may not be entirely representative of the clinic populations. This analysis involves the 211 subjects who had reported sexual activity within the previous month. The data are derived from baseline (pre-intervention) questionnaires completed between January 1987 and February 1988. The self-administered questionnaire consisted of fixed-response, Likert-type items and was available in both English and Spanish. Research staff were present on site to assist subjects who needed help in completing the instrument. Confidentiality was guaranteed; the results were not shared with methadone clinic staff. Subjects were paid $20 in two of the clinics and $10 in the third for completing the questionnaire. The questionnaire included measures of knowledge about AIDS and its transmission; drug use and needle sharing; sexual activities and condom use; and attitudes and beliefs related to condom use.

The dependent variable was condom use, measured by the item: "In the last month, how often did you (or your partner) use a rubber (condom) for sex?" ("Never," "sometimes," "most times," or "every time"). Responses to this question were reasonably internally consistent; subjects reporting at least some use usually disagreed with a different, negatively phrased item on condom use: "I almost never have sex using rubbers (condoms)" ($r = -.70$). For the analysis condom use was dichotomized as no use vs some use in the last month. The independent variables were drawn from theory and research on the determinants of condom use in the general population[6] and among gay/bisexual men.[15]

Results

Sixty-eight percent of the subjects did not use condoms at all in the previous month and only 11 percent used condoms every time for sex. Table 1 presents a multiple logistic regression on condom use. Variables independently related to condom use were: greater personal acceptance of condoms, greater partner receptivity to sexual protection, and recent entry to methadone treatment.

Discussion

The low rate of condom use among these subjects is consistent with findings from other surveys of addicts,[11,16] gay/bisexual men,[15] and the general population.[6]

The multivariate results indicate that norms and expectations within sexual partnerships exert the primary influences on condom use for these IVDUs. Condom acceptability (believing that condoms do not impair enjoyment of sexual relations and being willing to use condoms when requested by a sexual partner) was the variable most strongly associated with condom use. Perceived partner receptivity to suggestions of condom use and other sexual risk reduction was also directly related to condom use. That is, when individuals are amenable to condom use, and when sexual partners effectively communicate reciprocal willingness, there is greater likelihood of condoms being used in that relationship.

Beliefs, attitudes, and communication skills involving condoms can be addressed by methods such as cognitive-behavioral group work with addicts and, when possible, with their sexual partners.[17] In groups participants who already know that condoms do not interfere with sexual pleasure can encourage or challenge others to verify this for themselves; experience with condoms is likely to decrease resistance to

[a]Includes 5 "others."
[b]Entered in regression as a continuous variable. Odds ratio is for a 5-year age interval.
[c]Not entered in the logistic regression because of high association with next variable, "Living with a Sexual Partner."
[d]"Are you now living with someone with whom you have a sexual relationship?"
[e]"In the last month, how often did you shoot up any drugs?" and "In the last month, how often did you share a needle or works with someone?"
[f]"How many people with AIDS or ARC (AIDS-related complex) do you know personally?"
[g]"My gut feeling is, I'm going to get AIDS sooner or later."
[h]"I don't like using rubbers (condoms) because they sometimes break."
[i]The correct answers were summed for seven items: "You could get AIDS by having unprotected sex with a person who shoot drugs" (T); "only homosexuals can give you AIDS through sexual relations" (F); "pregnant women who carry the AIDS virus can pass it to their newborn children" (T); "anal intercourse is the only way sex can give you AIDS (F); "a positive AIDS antibody test means you could give the AIDS virus to someone through sex" (T); "you can give the AIDS virus to someone else by sex or needle-sharing even if you feel healthy" (T); "you can't get AIDS just by oral sex (F)." Higher knowledge = higher score. Entered in regression as a continuous variable.
[j]Two items were summed: "I don't like using rubbers (condoms) because they cut down on my enjoyment" (agree = 0, not sure = 1, disagree = 2); "I would use rubbers (condoms) if my partner asked me" (agree = 2, not sure = 1, disagree = 0). Higher acceptability = higher score. Entered in regression as a continuous variable.
[k]Two items were summed: "Using a rubber (condom) can help protect you from getting AIDS" (agree = 2, not sure = 1, disagree = 0); "there's no way to have 'safe sex' with someone who's carrying the AIDS virus" (agree = 0, not sure = 1, disagree = 2). Higher perceived efficacy = higher score. Entered in regression as a continuous variable.
[l]Two items were summed: "My sex partner would be insulted if I suggested that we use a condom" (agree = 0, not sure = 1, disagree = 2); "my sex partner would be insulted if I suggested any changes in the way we have sex" (agree = 0, not sure = 1, disagree = 2). Greater receptivity = higher score. Entered in regression as a continuous variable.
[m]Two items were summed: "I've already done plenty that could have exposed me to AIDS" (agree = 2, not sure = 1, disagree = 0); "I never did anything that could give me AIDS" (agree = 0, not sure = 1, disagree = 2). More exposure = higher score. Entered in regression as a continuous variable.
[n]Two items were summed: "I'm worried that some of my sexual partners could give me AIDS" (agree = 2, not sure = 1, disagree = 0); "I'm worried about my chances of getting AIDS" (agree = 2, not sure = 1, disagree = 0). Higher susceptibility = higher score. Entered in regression as a continuous variable.
[o]Odds ratio is for a 6-month interval. Entered in regression as a continuous variable.

continued

their use.[18] Participants can also practice communication and negotiation skills pertinent to sexual relationships. Even if neither partner personally objects to condom use, as our data suggest is often true, one partner must nevertheless take the initiative and broach the subject of use.

Addicts who recently entered methadone treatment were more likely to use condoms. This relationship requires more detailed investigation.

It is of particular concern that, of the 39 subjects (19 percent) planning on conception, only 20 percent reported being tested for HIV antibody (all seronegative). These findings held true equally for men and women. AIDS health education must emphasize the importance of HIV testing for IVDUs who wish to conceive, given the at least 30 percent risk that seropositive women will bear infants who will develop HIV-related illness.[19,20]

The study has several limitations. Causal interpretations should be considered tentative because the data are cross-sectional. The subjects were all in methadone treatment; an estimated 15 percent of IVDUs in New York City are in treatment at any given time.[21] It is possible that a study of street addicts would yield different results, but note that we found no association between current intravenous drug use and condom use for our sample (Table 1). Not all variables hypothesized or found to be associated with condom use in the research literature were measured by the study. These include a possible belief that condoms make sex seem premeditated, possible embarrassment in purchasing condoms, and the cost of condoms for low-income persons. The first two factors, however, have seemed particularly important only for adolescents.[22–24] The cost of condoms has become a less pertinent consideration for addicts since many drug abuse treatment programs (including the study clinics), as well as AIDS prevention outreach projects, have been distributing condoms for free.

ACKNOWLEDGMENTS

This study was funded by Grant No. R01 DA03281 (MAXIM) from the National Institute on Drug Abuse to Narcotic and Drug Research, Inc., in cooperation with the New York State Division of Substance Abuse Services. We are grateful for the support of this work given by Julio A. Martinez, Jr. (Director), Norwig Debye-Saxinger (First Deputy Director), and Charles LaPorte (Deputy Director for Chemotherapy), all of the New York State Division of Substance Abuse Services, and by David P. Glasel (President) and John Randall (Executive Director), both of Narcotic and Drug Research, Inc. The participating treatment programs were Albert Einstein College of Medicine—Division of Substance Abuse (Trailers 1 and 2) and Long Island Jewish/Hillside Medical Center—Methadone Maintenance Treatment Program. We wish to thank the following individuals for their valuable assistance in the conduct of this study: Peter Hartsock (Project Officer), Joyce Lowinson, Ira J. Marion, Frederick Siegal, Kenneth R. Amann, James Koger, Kathleen Sheehan, Richard Woytek, Charles McCarrick, Egidio Cafarelli, Lester Weisenfeld, John Langrod, Michael Rosenzweig, Steve Swain, Donald Thomas, Kevin Gehan, Theodora Owen, and Kathleen Fagan. The cooperation of all the staff and patients of the participating clinics is greatly appreciated. The opinions expressed herein do not necessarily reflect the official positions of the sponsoring or cooperating organizations. This paper was presented in part at the Fifth International Conference on AIDS, Montreal, Canada, June 4–9, 1989.

Results of an Intervention to Improve Compliance with Referrals for Evaluation of Suspected Malignancies at Neighborhood Public Health Centers

CLARA MANFREDI, PHD, LORETTA LACEY, RN, DRPH, AND RICHARD WARNECKE, PHD

Abstract: A study was conducted at Neighborhood Health Centers to evaluate procedures to improve compliance with referrals of patient at risk for cancer. Intervention consisted of a standardized communication from the exit nurse, a patient form to be returned after compliance, and one written and one telephone reminder as needed. Compliance was 68.2 percent in a control group and 89.0 percent among patients who received the experimental intervention, a significant increase of 20.8 percent (95% CI: 12.5, 29.1). (*Am J Pubic Health* 1990; 80:85–87.)

Introduction

Excessive cancer mortality among low income and minority populations could be reduced with better screening and earlier detection and treatment.[1–6]

Indigent populations rely upon public clinics for primary care which refer persons with suspected cancer to other medical facilities for further care; compliance with referrals is often problematic, contributing to delayed treatment.[7,8]

Delay in seeking care has been associated with difficulty communicating with physicians,[7,9,10] difficulty obtaining prompt appointments,[7,11] and concern about financial costs.[12–15] In contrast, compliance improved with prompt appointment dates, clear and specific instructions, and reminders.[7,11,16–18] Fear of cancer may be a deterrent to promptly seeking a diagnosis,[19,20] whereas knowledge of cancer symptoms and belief in the possibility of early detection and cure may lead to prompt diagnosis and treatment.[13,14,20–22] This study, however, focused only on intervention designed to improve referral information and remind those patients who may not have kept the referral appointment.

Methods

The study was conducted between October 1984 and January 1986 at four Chicago Department of Health Neighborhood Health Centers (NHCs). Subjects were adult medicine and maternal and family planning patients, at least 18 years old, without prior cancer history and referred for treatment or further diagnostic workup for a suspected cancer.

At the exit interview, nurses identified eligible patients and, in the experimental condition, administered the intervention. Overall, 292 control and 226 experimental group patients were accrued. No patient consent was needed because the intervention was an improvement on normal care and placed the subject at no risk. Monitoring procedures revealed that approximately 50 percent of eligible cases were not included in the study because of direct physician referral, missed opportunity by nurses to see the patient, nurse was too busy. Missed cases were more likely than those accrued to the study to be referrals for non-specific evaluation and to lack an appointment date, but occurred equally in the control and experimental conditions based on NHC assignment. Study results are based only on identified cases.

Unpredictability of case occurrence and need to integrate the study procedures into routine NHC's activities made random assignment to study conditions unfeasible. Instead, each NHC was assigned to experiment or control on alternate months, with two NHCs in either condition in any given month.

The experimental intervention consisted of:

- A verbal nurse-patient communication, structured with a mini-questionnaire designed to facilitate queries about referral procedures (i.e., why needed, where to go, whom to contact, etc.).
- A form, which patients were requested to return in a prestamped, pre-addressed envelope after referral completion.
- A reminder note, mailed to 163 patients (72.1 percent) whose chart had no return form nor other record of compliance two weeks after appointment or six weeks after referrals without appointment.
- A telephone reminder, attempted with 102 patients (45.1 percent) still without record of compliance three weeks later. Only 79 calls were completed, because patients could not be found or nurses could not make numerous attempts. Those not contacted by phone were sent a second written reminder and 13 patients were reminded of the referral as they revisited the NHC.

Control patients received the NHCs' usual referral procedures.

Compliance was ascertained by phone interviews. Interviews were attempted with all patients three weeks after final chart review and completed with 393. The remaining were: 106 not located, 15 with communication barriers, two deceased, and two refused. Completion was 75.3 percent in the control and 76.5 percent in the experimental group. Study results are based only on the 393 cases with final interview.

Results

Compliance was reported by 304 patients (77.5 percent). Of these, 61 (27.7 percent) of the control group and 73 (42.2 percent) of the experimental group also had documentation of compliance in their medical chart and 51 patients (29.5 percent of experimental group) had returned their patient intervention form.

Study patients were predominantly Black (69.5 percent), female (88.5 percent), 48 percent were under age 55, and 23 percent under age 35. Only 18.8 percent of referrals received

TABLE 1—Percent of Patients Who Complied with Referrals in Each Study Group, Overall and by Patient and Referral Characteristics

Variables	Control Group (N = 220) %	N	Experimental Group (N = 173) %	N	Per cent Difference	(95% CI)
Overall	68.2	(150)	89.0	(154)	20.8	(12.5, 29.1)
Sex						
Male	84.6	(22)	100.0	(19)	15.4	(−1.6, 32.4)
Female	66.0	(128)	87.7	(135)	21.7	(12.7, 30.7)
Race						
Black	64.7	(101)	87.2	(102)	22.5	(12.5, 32.5)
White	61.1	(11)	77.8	(7)	16.7	(−16.3, 49.7)
Hispanic	88.9	(8)	96.0	(24)	7.1	(−23.9, 38.1)
Others	81.5	(22)	94.7	(18)	13.2	(−6.5, 32.9)
Age (years)						
18 to 34	73.7	(28)	90.3	(28)	16.6	(−2.0, 35.2)
35 to 44	65.0	(13)	100.0	(25)	35.0	(13.4, 56.6)
45 to 54	69.6	(16)	79.3	(23)	9.7	(−14.0, 33.4)
55 to 64	63.3	(30)	87.5	(36)	23.7	(5.5, 41.9)
65 to 74	65.4	(34)	96.3	(26)	30.9	(11.0, 50.8)
75 or more	72.5	(29)	81.0	(17)	8.5	(−14.4, 31.4)
Education (years)						
Less than 9	71.6	(58)	92.2	(47)	20.6	(6.5, 34.7)
9 to 11	68.1	(49)	86.2	(150)	18.1	(3.4, 32.8)
12 to 14	67.2	(39)	89.5	(51)	22.3	(7.2, 37.4)
15 or more	44.4	(4)	85.7	(6)	41.3	(−6.5, 89.1)
Clinical Reasons for Referral						
Prior test results	81.6	(40)	97.1	(33)	15.5	(1.3, 29.7)
Symptoms only or missing information	64.3	(110)	87.0	(121)	22.7	(12.9, 32.5)
Procedure Requested in the Referral						
Evaluate, rule out	83.3	(50)	93.0	(53)	9.7	(−2.1, 21.5)
Mammography	54.7	(52)	84.1	(58)	29.4	(14.8, 44.0)
All others	73.8	(48)	91.5	(43)	17.7	(3.0, 32.4)
Appointments						
Within 15 days	92.9	(39)	96.9	(31)	4.0	(−6.4, 14.4)
Within 16 to 147 days	53.5	(38)	82.5	(52)	29.0	(13.1, 44.9)
No appointment	68.2	(73)	91.0	(71)	22.8	(10.7, 34.9)
Insurance Coverage						
Yes	67.5	(77)	89.6	(60)	22.1	(9.2, 35.0)
No	68.9	(73)	88.7	(94)	19.8	(7.9, 31.7)
Referral Hospital						
Cook County Hospital	60.8	(79)	86.8	(105)	26.0	(15.0, 37.0)
Other hospitals	78.9	(71)	94.2	(49)	15.3	(2.9, 27.7)

an appointment date within 15 days and 47.1 percent received no appointment. Almost half of the patients had no insurance and 63.9 percent were referred to the public county hospital.

Experimental group patients were more likely than controls to be Hispanic (14.7 versus 4.1 percent), lack insurance (61.3 versus 48.2 percent) and be referred to the county hospital (69.9 versus 59.1 percent).* Within the experimental group, patients who had received an appointment date were more likely to have returned their intervention form (36.8 percent) than those without an appointment date (20.5 percent).

Compliance with referrals was 68.2 percent in the control and 89.0 percent in the experimental group, an increase of 20.8 percent (Table 1). Characteristics associated with better compliance in both groups included: male gender, referrals following prior test results and for appointments within 15 days. Compliance was less likely for referrals for Blacks, for mammography, and for referrals to the county hospital.

Improved compliance was most evident for conditions associated with non-compliance in the control group. It was least evident for appointments within 15 days, which were associated with high compliance regardless of intervention.

The high appointment-keeping of patients with prompt appointments is striking and may be due partly to the latter being associated with more urgent medical conditions. Appointments within 15 days were more likely to be for follow-up of positive Pap smears (47.4 percent) than for positive guaiac or other laboratory results (28.9 percent) or for all other conditions (13.9 percent) and for referrals for surgical or other procedures (33.7 percent) than for evaluation (20.5 percent) or mammography (9.1 percent) (data not presented in tables).

Because the majority of patients in the study were Black females, results were analyzed separately for this group. Compliance among Black females was 61.9 percent in the control and 85.8 percent in the experimental group. Their patterns of compliance by patient and referral variables within study group were very similar to those reported in Table 1 for the entire sample.

Discussion

The study findings indicate that compliance with referrals can be improved when appointments are within two weeks of referral and when clinic staff give clear instructions and follow-up patients to ensure receipt of prescribed procedures. Even when the situation of the referral would predict poor compliance, careful attention by the clinic staff reduced the noncompliance significantly.

The majority of referrals in this study were for mammography and to follow-up positive Pap smears. Without the intervention, compliance with referrals following prior test results (thus including positive Pap smears), was 81.6 percent, but only about half of the women referred for mammography received the procedure.

ACKNOWLEDGMENTS

This study was supported by a grant from the National Cancer Institute, Department of Health and Human Services (CCSP No. 1 PSO CA34886). The authors thank the Chicago Department of Health and the administrators of the Neighborhood Health Centers for their cooperation and support. A special thanks is extended to all the nurses whose participation made the implementation of the study possible.

Parts of this paper were presented at the 114th annual meeting of the American Public Health Association, Las Vegas, Nevada, September 28–October 2, 1986.

APHA Invites Proposed Policy Statements for 1990 Consideration

The American Public Health Association has announced the schedule for the annual process of considering proposed policy statements. Individual members of APHA may submit resolutions. The various sections, affiliates, caucuses, SPIGs (special primary interest groups), and other components defined in the APHA constitution and by-laws may offer position papers.

Resolutions are short, single statements of 500 words or less, focusing on a specific action or series of actions endorsed by the Association, whereas a *position paper* is a major exposition, of up to 3,000 words, of the Association's viewpoint on a broader issue affecting the public's health. Each proposed statement will be considered by the APHA Joint Policy Committee which may recommend revisions to authors before the time of the APHA annual meeting. When the convention opens in New York City, open public hearings are held on all proposed policy, and the Governing Council takes final action by adopting or rejecting the proposed policy statements.

These public policy statements form the basis of APHA's stand on legislative, regulatory, legal, and health matters of concern to the public health community. They may stimulate scientific inquiry or be intended to initiate government action. The statements also provide a record of APHA's position on a variety of health issues, reflecting the diverse interest of the Association's membership, and further serve as a chronicle of changing and evolving public health concerns over the years of American history.

The *deadline* for receipt of proposed resolutions and position papers for consideration this year is *February 26, 1990*. A copy of the schedule and procedures is available from: Joint Policy Committee, APHA, 1015 15th Street, NW, Washington, DC 20005.

Plenum Books
CONTEMPORARY HEALTH ISSUES

ISSUES IN CONTEMPORARY INTERNATIONAL HEALTH

edited by **Thomas A. Lambo** and **Stacy B. Day**

Written by members of the World Health Organization, this work provides an overview of public health on an international level. Chapters discuss the economics of health care, international mental health care, international cancer care, health education, strategies for management, problem solving, support staffing, international funding, and more. The volume includes a complete list of current WHO International Health Regulations.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health,* 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5649.

Back Issues of the Journal: Published monthly since 1911, a limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Fecal Contamination of Shanty Town Toddlers in Households with Non-corralled Poultry, Lima, Peru

Grace S. Marquis, MS, Gladys Ventura, BS, Robert H. Gilman, MD, Esperanza Porras, BS, Elba Miranda, MS, Luz Carbajal, MS, and Marta Pentafiel, BS

Abstract: We used direct observer techniques to measure the frequency with which toddler-aged children were contaminated by poultry feces in homes in a peri-urban shanty town in Lima, Peru. The mean number of fowl was 5.4 (SD 3.1), with 10.0 (SD 10.7) poultry defecations per 12 hours. Toddlers' hand contact with poultry feces occurred a mean of 2.9 (SD 3.0) times/12 hours. A mean of 3.9 (SD 4.6) feces-to-mouth episodes per household/12 hours occurred both by direct hand-to-mouth contamination and indirectly by handling soiled objects which were then placed in the mouth. There was a strong correlation between feces-to-hand contamination and feces-to-mouth contamination (r = 0.94). There was also an association between feces-to-mouth contamination and the number of stools deposited in the house (r = 0.66). For each additional chicken stool deposited during the day, there was an average increase of 0.27 in feces-to-mouth episodes.

We collected feces from 68 infected chickens and found viable *Campylobacter jejuni* for up to 48 hours after deposition. Yet, a survey of 108 families demonstrated that free-roaming poultry were often not thought of as a health risk for children. An intervention program to reduce oral-fecal contamination should emphasize that all poultry be corralled and not allowed access into the house. (*Am J Public Health* 1990;80:146–149.)

Introduction

Diarrheal disease is an important factor in the infection-malnutrition cycle of infants and young children in developing countries. In Peru, children under three years of age have a diarrheal incidence of 10 episodes per child-year, which can significantly affect their growth rates.[1] One important cause of diarrhea in Lima children less than one year of age is *Campylobacter jejuni*. This organism was found in 15 percent of diarrhea stool samples[2] and accounted for the majority of dysenteric diarrheas.[3]

In Peru, *C. jejuni* has been isolated from 88 percent of commercial chickens and 50 percent of free-ranging domestic chickens in a pueblo joven (a peri-urban shanty town community).[4] In an aged-matched case-control study of Lima peri-urban households, children in families with chickens had a three-fold relative risk of having *C. jejuni* diarrhea which increased to 12.5 in families with *C. jejuni* infected chickens.[2] These risk factors suggest that direct contact with free-roaming *C. jejuni*-infected chickens that defecate on household surfaces is an important transmission vehicle for young children.

Direct observation of the personal hygiene of small children and mother-child behavioral patterns is the most reliable method for obtaining data.[5] We used directed observer techniques to measure the rate at which toddlers in a shanty town contaminate themselves with domestic poultry feces.

Methods

Study Sites

The study was done in two pueblos jovenes (recent shanty towns): Huascar, Canto Grande[6] and Las Pampas de San Juan, San Juan de Miraflores, in Lima Peru. The majority of the study population are rural immigrants who are daily laborers or street vendors with low, unstable incomes. Housing materials in Huascar and San Juan range from woven cane matting to permanent structures of brick and cement. Although the majority of pueblos jovenes do not have electrical installations, most of our study households had them. Water is scarce in both pueblos. It is provided through tanker trucks, and in half of San Juan through piped communal water spigot. In-house sewage systems are not available.

Direct Observation Data

Ten families from Huascar participated in an in-depth behavioral observation study, with a total of 21 children under five years of age. All the families had at least one child under two years of age, and domestic chickens which were not corralled at least part of the day. They gave informed verbal consent prior to their participation. The study received ethical approval by all involved Peruvian institutions (Universidad Peruana Cayetano Heredia, Instituto de Investigación Nutricional, and PRISMA - Proyectos en Informática, Salud, Medicina y Agricultura).

To gather the direct observation data, a field worker remained in the toddler's home for one 12-hour observation period (7am to 7pm). At the beginning of the visit, a descriptive inventory of the domestic animals was completed. During the 12-hour period the observer noted all activities in the house for each fowl, including the number of times the fowl entered the home, the duration of time spent inside, and how frequently and where the poultry defecated. The observer also tabulated the activities of the toddler, specifically noting the number of times the child's hands were contaminated with poultry feces (defined as feces-to-hand episodes) and the number of times that his/her hands, or other objects contaminated with poultry feces, were introduced into his mouth (defined as feces-to-mouth episodes). Feces-to-mouth episodes were considered to have been interrupted and were not tabulated if the child's contaminated hands had been washed before he placed them in his mouth.

All feces-to-hand and feces-to-mouth episodes were tabulated for each family and analyzed as episodes per child. Correlations and linear regressions for the feces-to-hand and

feces-to-mouth episodes were performed with the following variables: number of fowl, hours in the house/12 hours, and number poultry stools/12 hours.

Poultry Raising Practices and Beliefs

We surveyed a group of 108 families living in Las Pampas de San Juan to document their practices and beliefs regarding the raising of chickens and other fowl. The survey identified the reasons families gave for raising or not raising poultry, their beliefs about corralling the poultry, and the effect that confinement has on the growth and the health of the animal, the perceived advantages of raising chickens in the home compared to buying them commercially, and the mothers' perception concerning whether poultry roaming within the house presented a health risk to young children.

Socioeconomic Data

As part of a longitudinal study of *Enterobius vermicularis*, 121 randomly selected families from Huascar were included in a socioeconomic survey. The same data were collected for the Pampas families that participated in the poultry raising practices survey. The socioeconomic survey detailed age, sex, level of education, and occupation of all members of the family. Questions on housing quality included the materials used to build the house, number of rooms, ownership of functioning radios, televisions, and refrigerators, and presence or absence of a latrine. Finally the number and types of animals belonging to the home owners were also registered.

The practices and beliefs of mothers who did and did not raise poultry were compared using Chi square analysis. Each socioeconomic data set from the two pueblos jovenes was analyzed individually, and compared for socioeconomic indicators, using Student t test and Chi-Square analysis.

Survivability of *C. jejuni* in Deposited Chicken Feces

Stool samples were taken from *C. jejuni*-positive chickens, raised in a household in Huascar, Canto Grande. A cloacal swab was taken immediately after the chicken defecated and another swab was taken from the stool on the ground. These served as baseline samples. The stool sample, on the ground of a sun-exposed patio, was fenced in with a metallic wire and marked with its respective identification number and code. After 24 and 48 hours, additional samples were taken. All the samples were immediately placed in Cary Blair media containing Skirrow's antibiotic supplement,[7] and processed by direct plating on blood agar with Butzler's supplement.[8] Another sample was inoculated into thioglycolate broth supplemented with iron and the following antibiotics: vancomycin 10 μg/ml, polymyxin B 2.5 I.U./ml and trimethoprim lactate 5 μg/ml. The plates were incubated immediately while the broth was refrigerated for 24 hours and then plated with Butzler's agar. All plates were incubated at 37°C under microaerophilic conditions. Campylobacter species were identified based on colony morphology, oxidase production, and spiral appearance in the Gram stain.

Results

Direct Observation in the Homes

The interaction between toddlers and poultry was observed for a total of 119 hours in 10 Huascar households. The majority of the poultry were chickens (fowl/house = 5.4, chickens/house = 4.4). Three out of 10 families also had ducks and turkeys. Chickens and ducks only were allowed to roam freely through the house for about one-third of the 12-hour observation period (Table 1). The number of poultry and the time they were in the house were correlated (r = 0.64), as were the number of observed stools and the time the animals spent within the house (r = 0.86).

The children had approximately three feces-to-hand episodes per 12 hours (Table 1). The risk of feces-to-hand contamination was from both fresh stool and from that deposited several days previously but not removed from the household surfaces. In three households where no observed defecations occurred, hand and oral contamination still happened with stools that had been deposited prior to the day of observation. The two most important variables were number of droppings and number of minutes chickens were in the house.

There were about four feces-to-mouth episodes per child (Table 1). Children only rarely washed their hands after touching feces, and often put their fingers in their mouths, so feces-to-hand and feces-to-mouth episodes were highly correlated (r = 0.94); feces-to-hand episodes and the number of poultry accounted for 93 percent of the variation in the dependent variable—the number of feces-to-mouth episodes. Neither feces-to-hand nor feces-to-mouth episodes were related to the number of young children in study families. For each additional chicken stool deposited during the day, there was an average increase of 0.27 in feces-to-mouth episodes.

Poultry Raising Practices

One hundred and eight mothers from the Pampas de San Juan participated in the poultry raising practices survey. Eighty-one (75 percent) of the mothers were migrants, usually from the sierra zones. Whereas 88 percent (14/16) of the Lima-born mothers raised multiple types of poultry, only half of the migrant mothers raised other types of poultry in addition to chickens (27/54).

The major reasons given for a raising poultry (Table 2) included their use for home consumption and enjoyment of raising animals. The majority of mothers realized that commercial chickens were cheaper than those raised at home. When mothers were asked whether commercial or domestic chickens cost more, 77/108 (71 percent) thought the commer-

cial chickens were cheaper while only 22/108 (20 percent) thought the reverse.

In 83 percent (58/70) of the families, the poultry roamed freely for much of the day, with access into the house. This practice was explained in part by the belief of more than one-half of the mothers that the animals grew better when they were allowed to wander freely. Seventy four percent of the mothers not raising poultry and 68 percent of the mothers with poultry thought that there was a health risk or a negative hygienic aspect associated with free-roaming poultry.

Socioeconomic Data

Table 3 shows the socioeconomic indicators studied in both pueblo joven communities. No socioeconomic differences were found in families that did or did not raise chickens and other poultry.

Microbiological Results

Forty percent (27/68) of the stool samples from *C. jejuni*-positive chickens deposited in sun-exposed patios still had viable organisms demonstrable after 24 hours. At 48 hours, only 18 percent (10/57) of the samples were positive.

Discussion

Campylobacter jejuni infection most commonly occurs through human fecal-oral transmission or through contaminated food or water.[9–13] This transmission is difficult to document, unless direct observation of family hygienic practices is used. Stanton, *et al*, demonstrated that responses to 24-hour recall and knowledge-attitude-practices questionnaires do not reliably reflect observed hygienic household practices.[5] The direct observation method is a strength of this study. A limitation is that the sample size is small. These data nonetheless demonstrate that contamination of toddlers' hands with feces deposited in the house by free-roaming birds is extremely common in Peruvian pueblo jovenes. In Bangladesh, play areas of infants and toddlers were also seen to be contaminated with chicken feces in approximately 66 percent of the households.[14] Approximately one-half the Bangladeshi mothers claimed to have seen the child touching or eating animal feces during the previous two weeks.

Unwashed hands of toddlers in a pueblo joven are frequently contaminated with poultry feces. As 50 percent of the chickens in a pueblo joven are carriers of *C. jejuni*,[4] the health risk to these toddlers is evident. We found that few of these feces-to-hand episodes were interrupted by hand washing.

Many pueblo joven mothers do not believe that chicken stools provoke illness. Similar results were found in the Bangladesh study, where over one-half of the mothers also did not recognize animal feces as disease-producing.[14]

The absence of running water in pueblo jovenes and the high cost of the water used may be important factors discouraging hand washing. Even in developed countries where water is easily available, oral-fecal contamination is common. Direct observations in an English nursery school during an epidemic of shigellosis showed that 50 percent of the children had contaminated their hands with *Shigella sonnei* after using the school toilet. Moreover, one-third of the children handled their face or sucked their fingers after using the toilet.[15]

The risk of acquiring viable *C. jejuni* in the study area is augmented because the house floors are usually made of dirt or unfinished concrete, so the complete removal of poultry feces is difficult to achieve, and *C. jejuni* can survive in the ambient environment for several days. Even where water is plentiful, in homes with free-roaming chickens, it is not realistic to assume that mothers will be able to effectively interrupt transmission by handwashing.

In addition to *C. jejuni*, a small percentage (2 percent) of poultry were fecal carriers of *Aeromonas* species.[4] The relationship of this organism to diarrhea has not been established. None of the free-roaming chickens sampled excreted *Salmonella* species. In both Peru and Bangladesh,[1,16] *Sal-*

monella species is an infrequent cause of community epidemics of diarrhea.

The present study suggests similar socioeconomic background and characteristics of families with and without poultry in a pueblo joven population, making it difficult to identify a target population. In addition, an intervention program would have to overcome common beliefs that inherently encourage the transmission of *C. jejuni*. Many families raised uncorralled chickens even though they recognized that purchasing poultry was cheaper than home grown animals, believing that chickens grow better when they are corralled; and appreciated the risk in having chickens roaming freely through the house. This suggests that this behavior will be difficult to modify.

In Peru, as our data show, most individuals living in pueblo jovenes have access to mass media. Most children attend primary school. Both mass media and formal education in the school system could be utilized for intervention programs. These educational programs should emphasize the health risks to toddlers of raising free-roaming poultry within the household and the need to corral poultry and prevent their entrance into the house.

ACKNOWLEDGMENTS

We would like to thank Sra. Martha RauRau for her able field support; Drs. W. Spira, M. Bateman, and R. Black for advice; and J. B. Phu, D. Sara, and M. Mañuco for assistance. We also thank the communities of Huascar, Bayovar, and Pampas de San Juan for their collaboration. Financial support for this research was provided in part by Harvard University by means of a cooperative agreement with the US Agency for International Development. Additional funding was provided by the RG-ER fund and Smith Kline & French Company.

Initial analysis was presented as an abstract at the American Tropical Medicine and Hygiene meeting, November 1987.

8th Competition Announced for Health Professions Students

Dr. Louis W. Sullivan, Secretary of Health and Human Services, has announced the 8th annual national competition among health professions students for the "Secretary's Award for Innovations in Health Promotion and Disease Prevention." Winners will receive awards of $3,000 for first place, $2,000 for second, and $1,000 for third; up to 17 semifinalists will receive $250 each.

The competition is open to a broad range of health professions students enrolled in baccalaureate or higher degree programs affiliated with the Federation of Associations of Schools of the Health Professions, cosponsor of the competition. Those eligible to compete include students of medicine, osteopathic medicine, nursing, veterinary medicine, optometry, pharmacy, podiatric medicine, public health, health administration, health education, and allied health.

Papers should present innovative proposals for health promotion or disease prevention in the community, at the worksite, in an educational setting, or for a special population group.

The deadline for submitting entries is March 15, 1990. A paper must be submitted to the school attended by the author or authors. Papers will be judged first by the school and then by the professional associations. A departmental panel will make the final selections, and HHS Secretary Sullivan will announce the winners in July. For further information, contact Blake Crawford, Health Resources and Services Administration (HRSA), US Public Health Service, DHHS, 5600 Fishers Lane, Rockville, MD 20857; tel: (301) 443-3376.

HIV Seropositivity of Needles from Shooting Galleries in South Florida

Dale D. Chitwood, PhD, Clyde B. McCoy, PhD, James A. Inciardi, PhD, Duane C. McBride, PhD, Mary Comerford, MSPH, Edward Trapido, ScD, H. Virginia McCoy, PhD, J. Bryan Page, PhD, James Griffin, Mary Ann Fletcher, PhD, and Margarita A. Ashman, MS

Abstract: Needle/syringe combinations were collected from three shooting galleries in South Florida and tested for the presence of antibodies to HIV-1. Fifteen of 148 needles (10.1 percent) tested positive for HIV-1 antibody. Seropositivity rates did not vary by the day of the week of collection, nor by shooting gallery from which they were collected. When the needle appeared to contain blood residue, 20.0 percent were positive versus 5.1 percent with no blood residue. These findings suggest that needles/syringes used in shooting galleries are likely to serve as reservoirs and/or vectors of transmission of the HIV-1 virus, and that although visual inspection of the needle/syringe may be useful in lessening the chance for transmission, even the visually "clean" needles may result in transmission of infection. (*Am J Public Health* 1990; 80:150–152.)

Introduction

The self-reported sharing of needles and syringes, particularly those belonging to shooting galleries, has been consistently associated with increased risk for HIV-1 infection among parenteral drug users.[1–3] A shooting gallery is a place where addicts go to rent syringes and needles ("works") and to inject drugs.

Shared drug injection equipment can transmit HIV-1 by parenteral transfusion when residual, contaminated blood remains in previously used syringes and needles and that equipment is reused by another person. Blood residue is often present in the syringe because of the aspiration of venous blood into the syringe.

No one has assessed the extent to which equipment owned by shooting galleries is positive for HIV-1 antibodies. Recently a study of needle-and-syringe exchange programs in Sydney, Australia determined that antibodies for HIV-1 were present in 3.1 percent of 1,544 needle and syringe combinations exchanged at two exchange centers.[4] Risk of exposure to HIV-1 probably is higher in shooting galleries where a wide variety of people rent the same works and needle and syringe combinations are routinely reconditioned to extend their useful life far beyond the average nine uses reported by intravenous users in Miami who reuse or share personal works.

In order to examine the potential for HIV-1 transmission through the use of injection equipment available in high-risk settings, needle/syringe combinations were collected from shooting galleries frequented by parenteral drug users in Miami, Florida and were tested for antibodies to HIV-1. Although this study measures antibody and not the presence of an infectious dose of virus, these data help explain the association between shooting galleries and HIV-1 infection.

Methods

Selection of Shooting Galleries

Three shooting galleries located in Miami, Florida were selected as the sites from which to collect needle/syringe combinations. These were among the most frequently mentioned galleries that were attended by parenteral drug users enrolled in coordinated investigations of the natural history of HIV-1 and the evaluation of risk behavior reduction programs. Seroprevalence* among users enrolled in these studies is approximately 36.1 percent for Blacks who were not Hispanic, 30.2 percent for Hispanics,** and 8.9% for Whites who were not Hispanic. The majority of persons who frequented these galleries were Blacks who were not Hispanic. Each gallery was located in a different inner-city area known for high rates of drug use.

Field observations at eight additional galleries indicate that the modes of operation at the study sites were typical for area shooting galleries. Each was housed in the residence of the gallery operator. All three rented used works for $2 and had bleach or alcohol available for cleaning works, and none sold drugs. Heroin and/or cocaine, both available for purchase nearby, were predominant. Syringe and needle repair and cleaning occurred in these galleries but no observations were made specifically for these needles and syringes.

Needle/Syringe Collection

Access to the three galleries was gained through the efforts of a staff outreach worker who had established a variety of contacts with the intravenous drug using population. He was a follow-up worker who spent all of his time locating drug using participants of a longitudinal study. Because he was not an outreach worker in an HIV prevention program, the shooting gallery operators were less likely to feel pressure to manipulate the selection of syringes. Needle/syringe units that had been used in the shooting galleries during the previous 24-hour period were collected each morning by the follow-up worker during two one-week periods in 1988. In order to avoid possible bias by day of the week, no more than six units were collected per site per day. Wherever more were available, six were selected by the follow-up worker without regard to appearance or condition.

*Seroprevalence is based upon data from three coordinated studies of HIV infection among intravenous drug users (N = 1364) in Miami, Florida.

**The study population includes Hispanics who are White and Hispanics who are Black; they are Hispanic in culture and do not identify themselves as White or Black.

Each gallery operator was paid a flat fee of $24 per visit and did not participate in the selection of syringe units.

Each morning after collection, the needle and syringe combinations were immediately transported to the University of Miami and visually graded as follows:

1. "Visible Blood"—The needle/syringe appeared to contain liquid or dried blood.
2. "Dirty, No Visible Blood"—The needle/syringe contained visible dirt, or stains, but no blood.
3. "Clean, No Visible Blood"—The needle/syringe contained no visible dirt, stains or blood.

Needles were then delivered to the laboratory where they were tested for the presence of antibodies to HIV-1.

Laboratory Methods

A pilot study had been conducted with 17 needle and syringe combinations under conditions simulated to represent the condition of the needles/syringes which would be collected at the shooting galleries. Using the blood samples from a high-risk group whose blood was sent to the laboratory for routine testing, 200 μl of blood from each sample were drawn into a syringe and expelled. After standing overnight each needle/syringe was rinsed with 200 μl of saline and flushed 10 times with the saline solution. This solution was assayed twice by ELISA (Abbott Enzyme Immunoassay).

Ten samples from the test needle/syringe combinations were found to be reactive for HIV-1 antibodies confirmed by Western Blot and seven were non-reactive. These results were identical to the results of the routine testing for HIV-1 antibodies done on the blood samples.

Needle/syringe combinations collected from shooting galleries likewise were rinsed with 200 μl of saline, flushed 10 times and assayed in the same manner as the test needles. These procedures were similar to those used by Wolk[4] except that needles were tested more quickly and less saline was used in our study.

Needle/Syringes Not Tested

The field worker collected needle/syringe units regardless of condition or potential for testing or reuse. Sixty-two of the units collected could not be tested because of physical damage to the syringe (58 percent) or a clogged/damaged needle (48 percent). Needles and syringes were collected for three days during a subsequent week until 50 testable combinations had been received from each site. In two cases, results of HIV-1 testing were indeterminate on Western Blot, and were excluded from the analysis.

Analytical Procedure

Differences in proportions and 95 percent two-sided confidence intervals around the difference were calculated.

Results

Fifteen (10.1 percent) of the 148 needle/syringe combinations tested were found to be positive for HIV-1 (Site 1 = 10.2%; Site 2 = 12.3%, Site 3 = 8.0%) and 133 were negative (89.9 percent). There were no differences in seropositivity by day of the week on which needles were collected.

The relation between the graded condition of the needle/syringe combinations and the presence of HIV-1 antibodies is presented in Tables 1 and 2. Twenty percent of the equipment combinations which had visible remnants of blood had evidence of HIV-1 antibodies, compared to 5.1 percent in combinations without blood. Thus the risk of having an infected needle/syringe was approximately four times higher if the needle/syringe appeared to be bloody. No differences in seropositivity were observed when syringe and needle combinations which contained no visible blood were partitioned into clean (4.7 percent) and dirty (5.5 percent) categories (Table 2).

TABLE 1—Seropositivity of Needle/Syringe Combinations without and with Visible Blood

Appearance	Total Tested	Proportion HIV Ab+*
	N	%
No Visible Blood	98	5.1
Visible Blood	50	20.0

Clean	55	5.5
Dirty	43	4.7
Total	98	5.1

*Difference in proportions 0.008 (−0.06, 0.12)

Discussion

This study confirms epidemiological evidence that the use of needles belonging to shooting galleries can transmit HIV-1. Ten percent of the needle-syringe combinations which were tested from three shooting galleries were positive for antibodies to HIV-1. The use of such needles presents a clear public health hazard.

Shooting galleries provide needle and syringe combinations for "rent" to drug users. The combinations usually are held by the gallery operator or laid out on a table and are selected for use by either the operator or customer depending on house rules. Water and in some cases, alcohol or bleach, are available to rinse the works, i.e., to clean the syringe and needle. The custom in many galleries is to clean the works after injecting—not prior to injecting. However, there are no mechanisms to assure that works are cleaned after use and in many instances we found they were not cleaned. Moreover, cleaning often entailed simply rinsing with water rather than bleach or alcohol.

The data from this study suggest that the choice of clean-appearing injection equipment does not eliminate the possibility of using an HIV-1 infected needle. Needle and syringe combinations which contain visible blood were more likely to be positive for antibodies to HIV-1 than those that do not contain visible blood, but the selection of a needle without visible blood was no assurance of safety. This is important because drug users may mistakenly believe that they are capable of determining which used works are "clean" i.e., safe.

Works rented in most shooting galleries are returned for future use until they are no longer functional. In this study, 29.2 percent of the collected needle/syringe combinations were clogged and could not be tested. No attempt was made to test these non-functional needle/syringe combinations because of the risk of a needle stick or contamination by

laboratory personnel (who would have had to remove needles to test the contents of the clogged needle or syringe). However, 60 percent of the untested combinations contained blood residue while only 33 percent of those tested contained visible blood. Thus, our estimate of seropositive needle-syringe combinations probably is a conservative estimate of seropositivity in usable needle/syringe combinations which at the time they were collected were available for use by shooting gallery customers.

Our choice of shooting galleries was not by random sample and does not purport to represent all shooting galleries in the area. For obvious reasons, it is not possible to draw up an inclusive list of shooting galleries from which to randomly select representative galleries. However, those studied were three of the largest and most frequented galleries in the South Florida area. The operators of each gallery reported they serviced an average of 125 intravenous drug users per week and many of these clients rented works on more than one occasion.

As with other drug use issues, the solution to the problem posed by HIV-1 contaminated needles and syringes is not simple. Intravenous drug users frequent shooting galleries for a variety of reasons.[5,6] In communities such as Miami where new syringes may be purchased by prescription only and possession of drug paraphernalia is illegal, galleries provide the user with a place to inject which is relatively safe from police intervention. Shooting galleries increase the availability of needle and syringe combinations and some also sell drugs. Galleries provide a place where drug users can socialize with other drug users. At some locations prostitution is common. Even faced with evidence that shooting galleries are sources of HIV-1 infection, many users still frequent galleries.

Intervention programs must be developed to reach intravenous users who continue to use shooting galleries. Both the users and gallery operators need to be educated on the necessity of either using new works or cleaning works and need to be taught proper cleaning techniques. Gallery operators exercise control over injection behavior at their locations. If they become convinced that sterile needles and syringes are essential, those central figures could have considerable influence upon a large number of other users. For example, two gallery operators in Miami have been observed requiring all customers to purchase new works.

If risk reduction is to occur among users who continue to inject drugs, techniques to clean works must be incorporated into the value system of the operators of the galleries as well as the individual parenteral drug users and made a part of the shooting behavior of those users who frequent shooting galleries.

NIH Consensus Statement on Oral Complications of Cancer Therapies

On April 17–19, 1989, the National Institute of Dental Research (NIDR) and the Office of Medical Applications of Research (OMAR) of the National Institutes of Health (NIH) held a consensus development conference on *Oral Complications of Cancer Therapies: Diagnosis, Prevention, and Treatment*. After hearing presentations on the subject by scientific experts, a consensus panel issued its report containing the conclusions and recommendations of the conferees. Free single copies of the consensus statement may be obtained from:

William H. Hall
Directior of Communications
OMAR, NIH, Bldg. 1, Room 259
Bethesda, MD 20892
Tel: (301) 496-1143

OMAR will also provide multiple copies of a two-page summary of the consensus statement to organizations that wish to distribute it to members of their organization. Contact Mr. Hall's office and advise him of the number of copies required.

Occupational and Other Exposures Associated with Male End-Stage Renal Disease: A Case/Control Study

N. Kyle Steenland, PhD, Michael J. Thun, MD, MPH, C. William Ferguson, BA, and Friedrich K. Port, MD

Abstract: We conducted a case-control study of 325 men ages 30–69 who were diagnosed with end-stage renal disease (ESRD) between 1976 and 1984, and resided in four urban areas of Michigan in 1984. Cases were selected from the Michigan Kidney Registry and excluded men with diabetic, congenital, and obstructive nephropathies. Controls were selected by random-digit dialing and were pair-matched to cases for age, race, and area of residence. Telephone interviews were conducted with 69 percent of eligible cases and 79 percent of eligible controls. Risk of ESRD was significantly related to phenacetin or acetaminophen consumption (odds ratio(OR) = 2.66), moonshine consumption (OR = 2.43), a family history of renal disease (OR = 9.30); and regular occupational exposures to solvents (OR = 1.51) or silica (OR = 1.67). Particular occupational exposures with elevated risk were solvents used as cleaning agents and degreasers (OR = 2.50) silica exposure in foundries or brick factories (OR = 1.92), and silica exposure during sandblasting (OR = 3.83). Little or no trend of increased risk with duration of exposure was found for these occupational exposures, with the exception of silica in sandblasting. Limitations of these data include representativeness of cases, possible overreporting by cases, and misclassification of exposures inherent in self-reports. (*Am J Public Health* 1990; 80:153–159.)

Introduction

End-stage renal disease (ESRD) is a major public health problem in the United States. In 1985, over 120,000 Americans suffered from ESRD, and each year approximately 30,000 new cases arise. Cases require dialysis or transplant, and the current annual cost exceeds $2 billion a year, almost entirely paid for by the federal government.[1] Yet very little is known about the causes of ESRD. A minority of ESRD cases are characterized etiologically (e.g., lead nephropathy, analgesic nephropathy, diabetic nephropathy).[2] Many cases are described histologically (e.g., glomerulonephritis, interstitial nephritis). Others are described as "hypertensive nephrosclerosis," with no determination of whether the kidney damage preceded or followed the hypertension.

Acute exposures to heavy metals can cause acute renal disease or dysfunction. There is also some indication that occupational exposures to metals, solvents, and silica may play a role in chronic renal disease.[2] Evidence indicates excess renal disease among workers exposed chronically to uranium,[3] cadmium,[4] and lead.[5–8] In addition, animal studies have shown that high exposures to carbon tetrachloride or perchloroethylene can also cause acute kidney damage.[9] In recent years, case-control studies have indicated that chronic glomerulonephritis is associated with occupational exposure to hydrocarbons.[10–15] Evidence of silica-related renal disease is limited to case reports[16,17] of acute renal failure following high exposures to silica.

To further investigate the hypothesis that occupational exposures might be associated with end-stage renal disease, we have conducted a case-control study of males diagnosed with ESRD between 1976–1984 in four urban areas of Michigan.

Methods

Cases

Patients were identified from the Michigan Kidney Registry,[18,19] which registers all new cases of ESRD in Michigan, collects demographic data, and records the diagnosis provided by the attending physician at the time of the ESRD diagnosis. Eligible cases were all men diagnosed between 1976 and 1984 with selected diagnoses of ESRD, ages 30–69 at diagnosis, and living in four urban areas in southeastern Michigan in 1984. Cases were restricted to those still living because of the unreliability of next-of-kin for reporting detailed exposure history. Diagnoses excluded were diabetic nephropathy, polycystic kidney disease, heroin nephropathy, lupus nephropathy, nephropathy due to malignancy, Alport's syndrome, unspecified chronic renal failure, nephropathy due to obstruction, and a variety of less common nephropathies grouped as "other." These diagnoses were excluded because most have known nonoccupational causes. The diagnoses included were glomerulonephritis, hypertensive kidney disease (nephrosclerosis), and interstitial kidney disease (including pyelonephritis, lead nephropathy and other unspecified interstitial disease). These diagnosis included represented about 65 percent of the ESRD patients in Michigan.

The summary diagnoses in the Michigan Kidney Registry may not be accurate, since many of ESRD patients present with advanced disease, and only an estimated 5 percent or less of ESRD patients have been biopsied. For example, some physicians may have classified a case as nephrosclerotic on the basis of high blood pressure at the time of diagnosis, without further data indicating that the high blood pressure preceded the kidney disease. While the diagnoses available to the Registry were sufficient to exclude certain well-defined entities such as diabetic nephropathy, the diagnoses of the cases which were included (nephrosclerosis, glomerulonephritis, and interstitial nephritis) were not clearly differentiated one from another, and were therefore analyzed together.

The Michigan Kidney Registry identified 612 eligible cases. Contact was initially made by mail, with phone calls to nonrespondents. Eighty-seven of these men had died prior to any attempt to contact them, and 14 died after consenting to be interviewed but prior to being interviewed; another 26 men were found upon interview to be ineligible because they had kidney disease subsequent to diabetes or prolonged heroin use; and 14 men could not participate either because they were in prison or were mentally incompetent. Of the remaining 471 men, we interviewed 325 (69 percent). More nonre-

spondents than respondents were Black (67 percent vs 44 percent) and were living in inner Detroit (61 percent vs 40 percent).

Controls

Controls were chosen from the general population in the four urban areas of the study, via random-digit dialing. Controls were pair-matched to cases on age (within five years), race (White versus other), sex, and residential area based on telephone prefix, grouped in 15 geographical areas covering the entire study area. Men who had chronic kidney disease were excluded.

Random digit-dialing was conducted according to a modified Waksberg method[20] from February to October 1985. A potential control identified in calling the randomized number was allowed to match any case of the same age and race in the same geographical area. If numbers did not answer, repeated phone calls were made varying the time of day and day of week prior to abandoning the phone number.

A total of 3,962 numbers were called (with an average 1.95 calls per number). Of these, 61 percent (2,430) were working residential numbers. Twenty-three percent (567) of those who answered at a residential phone refused to provide initial information about males in the household. Once a household did provide such initial information and proved to have an eligible male, 79 percent (325/410) agreed to be interviewed. We compared the 325 controls (respondents) with the 85 individuals who were eligible but refused the interview (refusals). Potential controls who refused differed from respondents regarding race (55 percent Black versus 44 percent), and residence (60 percent from inner Detroit, versus 40 percent).

Interviews

Telephone interviews lasting 30–45 elicited demographic, medical history, and occupational histories. Cases were interviewed from November 1983 through December 1985, while controls were interviewed from March 1985 to January 1987. Interviewers knew which respondents were cases from the answers to a variety of questions. Neither cases nor controls were aware of the hypotheses of the study.

Respondents were asked about regular moonshine use, regular pain pill use, family history of serious kidney disease, years of education, smoking, lead poisoning, injected antibiotics, and environmental exposure to metals and solvents. Exposures were truncated at the year of diagnosis as end-stage for cases and their matched controls. Phenacetin or acetaminophen use was determined by a review of answers to a question about the use of pain pills on a regular basis (more than one pill per week for two years or more). Brands of analgesics were classified by whether or not they contained phenacetin or acetaminophen in the early 1970s, based on data provided by Dr. Dale Sandler at the National Institute of Environmental Health (personal communication). Acetaminophen was grouped with phenacetin because it is a metabolite of phenacetin and may also be associated with renal disease.[21]

Family history of renal disease was considered positive if kidney disease (excluding stones and cancer) occurred among parents, children, or siblings, and was not known to have occurred subsequent to diabetes or trauma.

Each job held for more than six months since age 18 was classified for occupation and industry using 1980 US Census codes.[22] For each job, questions were asked regarding regular exposure to solvents, metal particles, metal fumes, mercury, oil and gasoline, and ammonia. Ammonia was included as a check, since it was not thought to be related to kidney disease. For each material, details of the exposure (e.g., hours per week, process description) were recorded. Work history for cases and their matched controls was considered only up until the year of the diagnosis as end-stage for the case.

We reviewed the completed interviews without knowledge of case-control status and with the assistance of NIOSH (National Institute for Occupational Safety and Health) industrial hygienists. For positive responses to questions about metal fumes, metal particles, solvents, and silica, we created sub-categories by type of solvent, metal, etc (Table 2). When an individual had been unable to recall the number of hours per week during which he was exposed, we arbitrarily assigned five hours a week for infrequent exposure, 20 hours a week for frequent but not constant exposure, and 40 hours a week for constant exposure. In a few cases, a self-reported exposure to a substance was clearly wrong due to misclassification by the respondent, and we corrected the response (e.g., self-reported exposure to solvents such as "lime" or "pesticides"). In other cases, we called a respondent back for clarification.

Analysis

Odds ratios (OR) were estimated from conditional logistic regression.[23] Odds ratios for exposure were adjusted for confounding by nonoccupational variables and other occupational variables. Dummy variables (missing versus not exposed) were added to the model to account for those instances in which study subjects were missing data for lifestyle variables. When subjects were missing data on exposure, they were called again to resolve the problem. No cases or controls were lost at the analysis stage due to missing data.

We compared the occupational history of cases and controls in several ways:

- We considered a history of having ever been exposed to specific substances (e.g., all solvents, or solvents used as degreasers).
- We estimated cumulative exposure by multiplying the number of hours per week a man was exposed by the number of years in the job for each job, and summing over all jobs.
- Finally, for solvents, we used an exposure matrix developed by Shalat and others[24] to identify jobs likely to have involved high exposure to solvent (see Appendix). Cases and controls were then compared regarding work in these jobs. Analyses were also run which discounted any exposures (lifestyle or work history) which occurred in the five years preceding the date of diagnosis of the case.

Results

Table 1 gives the frequency of a number of lifestyle variables among (unmatched) cases and controls. After controlling for confounding by years of education and date of birth, phenacetin/acetaminophen use and moonshine use were both significant predictors of kidney disease, with odds ratios of 2.66, (95% confidence intervals 1.04, 6.82) and OR 2.42 (95% CI 1.10, 5.36), respectively. Cumulative measures of exposure for these variables showed positive but nonsignificant trends of increased risk with increased duration of use. The findings for family history were the most remarkable, with cases much more likely than controls (OR 9.30, 95% CI 7.99, 10.82) to have a close family member (parent,

TABLE 1—Demographic Characteristics of Study Population

Characteristics	Cases (n = 325)	Controls (n = 325)
Average years of education	11.7	12.5

Regular moonshine use	31	10
Regular use of phenacetin/acetaminophen	22	7
Current cigarette smokers**	143	151
Former cigarette smokers	119	91
Average years smoked, current smokers	35.8	34.4

*93% of non-Whites were Black.
**Includes men who quit within one year prior to their diagnosis.

child, sibling) with kidney disease (excluding kidney stones and kidney disease subsequent to trauma or diabetes). When any exposure within five years of the date of diagnosis of the case and his matched control was ignored, the results for moonshine consumption were unchanged, while the odds ratio for phenacetin/acetaminophen fell slightly from 2.66 to 2.47 (0.86, 7.12).

Controls were more likely ever to have worked in jobs as professionals, managers, or technicians (56 percent vs 46 percent). The most common industry for both cases and controls was the automobile industry, in which 51 percent of cases and controls had worked. The next most common was construction (17 percent), followed by foundries (9 percent), and hospitals (6 percent).

Table 2 presents the results of a logistic regression for occupational variables. Adjusted odds ratios were significantly elevated for exposure to solvents used as degreasers and silica used in foundries or in sandblasting. An elevated odds ratio was also observed for exposure to lead. No interaction terms were significant between any exposure variables and any lifestyle variables or other exposure variables.

Most men exposed to solvents used as degreasers worked in metal manufacturing industries (Census codes 271–370, 47 cases, 22 controls). Within this sector, the principal industry was auto manufacturing (32 cases, 17 controls). About equal numbers of cases and controls were exposed in dry cleaning shops (six cases, five controls). The subcategories of silica with elevated risk were exposure in foundries, brick making, or sandblasting, which were the categories likely to have involved the highest exposures.

There were no strongly positive trends of increased risk with increased duration of exposure for any exposure variable, with the exception of silica used in sandblasting. The odds ratio for exposure to silica in sandblasting for 2.5 years for 40 hours a week (cumulative duration = 100, an average exposure) was 2.74 (.69, 9.97).

We also considered employment in jobs considered to have had high solvent exposure (see Appendix). There were no differences between cases and controls regarding either ever having worked in these jobs (31 cases, 30 controls) or the length of time having worked in these jobs (5.3 years for cases, 6.8 for controls).

The above results for occupational variables were changed little when all exposures in the five years preceding the date of diagnosis of the case (and matched control) were ignored. For example, the odds ratio for ever having been exposed to solvents increased from 1.51 to 1.68 (1.13, 2.48), while the odds ratio for ever having been exposed to silica increased from 1.67 to 1.81 (1.09, 3.02). The coefficients for cumulative duration of exposure also were affected only slightly (for solvents, the coefficient changed from −.0000095 to .00009, while for silica it changed from −.0039 to −.0004).

Discussion

This study suffered from several limitations inherent in an interview study of ESRD patients. First, patients are often

TABLE 2—Adjusted Logistic Regression Results for Occupational Variables

Exposure	Number Cases Exposed	Number Exposed	Odds Ratio* (95% CI) Ever-Never Exposed*

quite ill and difficult to interview. This may contribute to a high refusal rate. Second, 482 men had been diagnosed between 1976–84 and would have been eligible for our study but had died by 1984, so that our study was of a population of survivors. A demographic analysis of those who died before they could enter the study indicated they differed little on race or residence, but were approximately five years older than men who were studied. A bias in our results could exist if these decedents differed substantially in their occupational exposures with those who survived to be studied. It is possible, for example, that those who died were of lower socioeconomic status and had different exposures than those who survived, although it is not clear that this would either increase or decrease odds ratios. We did not attempt to use of surrogate interviews by next-of-kin because next-of-kin could not report the decedent's detailed occupational histories. Third, it is difficult to study separate diagnostic groups among ESRD patients. We did not have confidence that the summary diagnosis in the Registry was sufficiently accurate to allow us to divide our data into the principal diagnostic groups (glomerulonephritis, nephrosclerosis, pyelonephritis) for diagnosis-specific analyses. Many of the above difficulties could be overcome by studying individuals with less severe kidney disease, prior to end-stage. With little data available to date, it is not clear whether occupational associations are more or less apparent in patients with end-stage versus less severe disease.

As in many case-control studies, we relied on self-reports to determine exposures. Cases may have had a tendency to overreport exposures compared to controls. We included a variable (ammonia exposure) thought not to be related to renal disease to test such overreporting. Cases did report more exposure to ammonia than did controls, although numbers were small and the difference was not statistically significant. Complicating any assessment of overreporting among cases was the fact that cases were more likely to have had less education than controls, and were more likely to have worked in blue-collar jobs than controls. Hence, they were more likely to have truly been exposed to occupational agents. This increased likelihood of "blue collar" status among cases compared to controls may have been an artifact of the random-dial dialing process. An alternative explanation is that our findings may represent a real phenomenon, whereby people with renal disease are of a lower socioeconomic strata than those without renal disease. While the published literature provides little data to support this thesis, one recent report reached similar conclusions.[21] To control for the observed confounding effects of socioeconomic class in our study, we have included a variable in the model for years of education.

Regarding nonoccupational variables, the effect of moonshine on renal disease is presumably due to contamination by lead.[25] Other studies have indicated that analgesics, particularly phenacetin, may be associated with renal disease (see the consensus report[26]).

Regarding occupational variables, our findings of elevated risk associated with self-reported exposure to solvents (used as cleaning agents or degreasers) and silica (used in foundries or brick manufacturing, and in sandblasting) are consistent with reports of renal disease resulting from acute exposure to these substances. An effect of solvents on chronic renal disease has also been seen in case-control studies.[15]

The lack of trend with duration of exposure to solvents can be seen as weakening the observed association between solvents and ESRD. However, duration of exposure may be a poor surrogate for cumulative dose, if those with short-term exposures also have higher exposures. Similarly, the negative findings for solvents using the pre-defined "high exposure" jobs may be due to the insensitivity of the job-exposure matrix which we used. Few attempts have been made to validate job-exposure matrices (none had been attempted for the one we used), and when such attempts have been made results have not always been encouraging.[27]

The covariate with the strongest association with renal disease in our study was a history among close relatives (parents, children, siblings) of renal disease (other than stones, or kidney disease subsequent to cancer or trauma). Due to the extremely strong association (odds ratio 9.3) observed for this variable, it seems unlikely that this positive association was due to overreporting. Familial patterns are known to exist for a number of relatively rare kidney diseases, but many of these would have been excluded from our case series (e.g., Alport's syndrome, polycystic kidney disease). Family history of hypertension, however, was not examined in our study, and may have contributed to the positive association we observed.

In summary, this study found a number of associations with ESRD which, in our opinion, warrant further investigation. These associations were generally supported by other data in the literature. The epidemiology of chronic renal disease is a relatively new area of investigation with many potential benefits, in light of the high prevalence of renal disease, its high mortality rate, and its high cost of treatment.

ACKNOWLEDGMENTS

This study could not have been done without the work of interviewers Marian Coleman, Claire White, B. J. Haussler, and Barbara Jenkins. Deciphering, coding, and computerizing of the interview data was accomplished by Kathy Watkins and Barbara Jenkins. Creating the appropriate SAS variables from the raw data was accomplished by Patti Dill. Dr. Letitia Davis (Massachusetts State Department of Health) kindly provided the US census codes converting the original SOC/SIC codes used in the job exposure matrix. Dr. Dale Sandler (NIEHS) kindly provided information regarding which pain pills contained phenacetin or acetaminophen.

Sentinel Health Events (Occupational): Analysis of Death Certificates among Residents of Nassau County, NY between 1980–82 for Occupationally Related Causes of Death

JUDITH P. FELDMAN, MD, MPH, AND LINDA M. GERBER, PHD

Abstract: Death certificates for residents of Nassau County, New York dying between 1980 and 1982 were examined for causes of death defined as Sentinel Health Events (Occupational) {SHE(O)}. Of 16,193 deaths from all causes, 2,286 (14.1 percent) were identified as SHE(O) deaths; 142 required no match because the cause of death was inherently related to the occupation or industry. Malignant neoplasms of the trachea, bronchus, or lung were the most frequently occurring SHE(O), accounting for 60 percent of all SHE(O) deaths and 81 percent of matched SHE(O) deaths. The construction industry was associated with the vast majority of such deaths. (*Am J Public Health* 1990; 80:158–161.)

Introduction

Although accurate numbers of job-related injuries, illnesses, and deaths are difficult to obtain, estimates suggest that two to 10 million injuries, 14,000 accidental deaths, and 100,000 occupationally related illnesses result annually from workplace accidents and exposure.[1,2]

Recognition and surveillance of occupationally related deaths are difficult since only 28 of 50 states routinely code industry and/or occupation (I/O) data on death certificates,[2] and methods of record keeping, sorting and coding are not standardized.

Rutstein, *et al*, have suggested a system to identify preventable occupationally related diseases, or Sentinel Health Events (Occupational), [SHE(O)].[3] Recognition of SHE(O)s may aid in the control of occupational diseases by providing the impetus for epidemiologic or industrial hygiene studies, or serving as a warning signal that material substitution, engineering control, or personal protection of medical care may be required.

New York State is one of several states that routinely codes I/O data on death certificates. The New York State Department of Health had recently implemented coding occupational and industry entries on death certificates according to the US Bureau of the Census coding system,[4] and, at the time this study was undertaken, had completed coding on death certificates between 1980 and 1982.[5]

Nassau County on Long Island has a population of 1.3 million,[6] and a diverse industrial and occupational makeup.[7,8] Because of its large population and varied economic environment, a study was developed to implement Rutstein's SHE(O) system to analyze occupationally related disease patterns and examine whether any particular examples of occupations or industries put workers in Nassau County at increased risk for disease.

Methods

All death certificates recorded by the New York State Department of Health for residents of Nassau County whose age at death was between 18 and 74 years, and whose date of death was between January 1, 1980 and December 31, 1982, were examined. Death certificates had been assigned an ICD(9) code based on the diagnosis most likely to have been the underlying cause of death. In addition, a code was assigned for both the occupation and industry listed on the certificate.

Using Rutstein's list of occupations and industries, death certificates whose cause was on the SHE(O) list were sorted into five categories: 0 = unmatched to occupation and industry; 1 = match on industry only; 2 = match on occupation only; 3 = match on both occupation and industry; and 4 = no match needed since listed cause of death was considered to be inherently related to occupation regardless of listed occupation or industry (e.g., mesothelioma).

Categories 1–4 were grouped as "SHE(O) deaths with I/O match" and compared by sex, age, race, occupation, and industry to the total deaths from all causes and to the total SHE(O) deaths (matched and unmatched).

Results

The 50 SHE(O) categories suggested by Rutstein are listed in the Appendix. Only 26 were identified as the underlying cause of death on one or more death certificates in Nassau County (shown with an asterisk in the Appendix.) There were 16,193 deaths from all causes of which 2,286 (14.1 percent) were SHE(O) deaths and 142 (0.9 percent) were matched SHE(O) deaths.

Despite the fact that males made up only 47.8 percent of the population between ages 18–74, they accounted for 60.3 percent of deaths from all causes, 66.3 percent of all SHE(O) deaths, and 90.1 percent of matched SHE(O) deaths.

Malignant neoplasms of the trachea, bronchus, or lung (respiratory tract neoplasms) were the most frequently occurring SHE(O), accounting for 59.5 percent of all SHE(O) deaths. The other frequently encountered SHE(O)s were cirrhosis of the liver without mention of alcohol [10.4 percent of all SHE(O)s], malignant neoplasms of the bladder [5.2 percent of all SHE(O)s], and malignant neoplasms of the kidney [5.7 percent of all SHE(O)s] (Table 1).

Of the 2,286 SHE(O) deaths, 142 (6.2 percent) were matched; of those, 117 (82.4 percent) matched on industry alone, 13 (9.2 percent) required no match, 11 (7.7 percent) matched on occupation alone, and one (0.7 percent) matched on the combination of industry and occupation.

Although respiratory tract neoplasms accounted for the largest proportion of the SHE(O) deaths, only 8.4 percent of

Chronic renal failure	28	1 (3.6)
Renal failure-unspecified	39	1 (2.6)
Total	2286	142 (6.2)

them were matched. Although 14.3 percent of non-A, non-B hepatitis, and 11.1 percent of tuberculosis cases were matched, the absolute numbers (one each) that were matched were very small. The 12 mesothelioma and one coal workers' pneumoconiosis were matched in 100 percent of the cases, but these diseases are by definition matched on diagnosis alone and fall into category 4 of "no match needed" (Table 2).

The 114 industry-matched respiratory tract neoplasms accounted for 80.3 percent of all matched deaths and 97.4 percent of all industry-matched deaths. Of the 13 deaths that required no match, 12 (92.3 percent) were due to mesothelioma (Table 3). For all respiratory tract neoplasms, the most commonly listed occupations were "housewives" (16.1 percent) and "managers and administrators not elsewhere classified" (8.4 percent); the most commonly listed industries were "private homes" (housewives) (16.2 percent) and "construction" (7.6 percent). For matched respiratory tract neoplasms, "construction laborers, plumbers, pipefitters and steamfitters, carpenters, construction supervisors not elsewhere classified" (7.8 percent) and "managers and administrators not elsewhere classified" (7.8 percent) were the most frequently reported occupations. "Construction" (87.0 percent), and "miscellaneous fabricated metal products" (5.2 percent) were the most frequently reported industries.*

Discussion

While the categories of SHE(O)s that were identified probably reflect the occupational, industrial, and environmental make-up of Nassau County, they might also reflect a lack of time or interest on the part of physicians in obtaining occupational histories. For example, despite the fact that there were 12 reported deaths from mesothelioma (virtually always caused by asbestos and usually easily recognized), there were no reported deaths from asbestosis (also caused by asbestos but not easily recognized in the absence of a good occupational history).

That men accounted for 60.3 percent and women only 39.7 percent of deaths from all causes can be explained by the fact that only ages 18–74 were analyzed. Women have a life expectancy at birth of 7.5 years greater than men.[9] Similarly, the fact that Whites accounted for 92.0 percent of all deaths

*Additional details available on request to author.

TABLE 3—Underlying Cause of Death by Type of Match, SHE(O)s Only

Underlying Cause of Death	Total with Match	Industry Only	Occupation Only	Both I and O	No Match Needed
Pulmonary TB	1	0	1	0	0
Cirrhosis of liver without alcohol	8	1	7	0	0
Hepatitis-non-A, non-B	1	0	0	1	0
MN larynx	2	2	0	0	0
MN trachea, bronchus, or lung	115	114	1	0	0
Mesothelioma (all)	12	0	0	0	12
Coalworkers' pneumoconiosis	1	0	0	0	1
Chronic renal failure	1	0	1	0	0
Renal failure-unspecified	1	0	1	0	0
Total	142	117	11	1	13

can be explained by the fact that Whites make up 91 percent of the total population of Nassau County.[8]

Women accounted for a disproportionately small number of deaths in the SHE(O) category and in the matched SHE(O) category. Many of the diseases listed as SHE(O)s have a latency period of 10–30 years. Deaths in 1980 from SHE(O)s might well be a result of exposure in the 1950s and 1960s when only 25–30 percent of the women were in the labor force.[10] Moreover, many women are classified as "housewife" on their death certificates. Those who may have died from an occupationally related illness would not be identified through this system.

The most striking findings of this study are that while respiratory tract neoplasms accounted for only 8.4 percent of all deaths, they accounted for 59.5 percent of all SHE(O)s and 81.0 percent of the matched SHE(O)s, and that while the construction industry was associated with only 5.9 percent of all deaths and 6.6 percent of all SHE(O) deaths, it was associated with 72.1 percent of all matched SHE(O) deaths and 87.0 percent of all matched deaths from respiratory tract neoplasms. It is difficult, however, to interpret these findings. Although in the construction industry asbestos is a major risk factor for lung cancer, smoking is the single most important cause of these deaths, and enhances the carcinogenic risk of asbestos.[11] Since laborers tend to be heavy smokers,[12] the apparent high proportion of respiratory tract cancers among construction workers may be due to the increased rate of smoking in this population, as well as to asbestos exposure. Smoking history was not available on the death certificates.

Death certificates have other limitations. The accuracy of occupational data on death certificates when compared to information obtained from medical records, union records, and personal interviews has ranged from 51 to 93 percent.[13–16] Occupational data requested on the death certificate is for "usual occupation' " with space for only one entry. However, few people work in a single job or are exposed to a single agent in a working lifetime. Because of the latency period for many diseases, an early job with toxic exposure may not be the "usual job" listed. Occupational categories are general, and there is no information on actual job description, or working conditions.

Finally, because of the latency period for many diseases on the SHE(O) list, the use of the death certificates to evaluate occupational exposure gives information in many instances on exposure that occurred years ago. Since people move, exposure and death may not necessarily have occurred in the same geographic area, thus limiting the usefulness of death certificates in pinpointing occupational hazards except for substances causing diseases with relatively short latency periods.

As the number of potentially toxic substances added to the workplace grows, it becomes increasingly important to identify occupations and industries that pose a threat to workers' health. Rutstein's scheme is an innovative step toward that goal. However, the limitations of death certificates underscore the need for further work in this area, especially for improved reporting systems and data collection methods.

One promising step in that direction is the implementation by the New York State Department of Health of occupational registries for individuals in certain high-risk jobs, with exposure to known carcinogens, or with traces of certain heavy metals in their blood. All businesses employing 100 or more people are required to report annually to the State the names of those employees who fall into any of the aforementioned categories. Such individuals could then be followed for early disease that might be related to their on-the-job exposures.

ACKNOWLEDGMENTS

We would like to thank Dr. Andre Varma of State University of New York at Stony Brook, and Gene Therriault of the New York State Department of Health for their assistance with this study.

A Statewide Case Registry for Surveillance of Occupational Heavy Metals Absorption

MICHAEL E. BASER, MS, AND DAVID MARION, BA

Abstract: The New York State Heavy Metals Registry is a legislatively mandated program through which clinical laboratories, physicians, and health facilities report state residents 18 years of age and older with elevated levels of lead, mercury, arsenic, or cadmium in blood or urine. From 1982–86, the current employer was determined for 95.9 percent of 3,309 cases. Occupational exposures in 328 companies accounted for 82.8 percent of cases. The majority of companies were reported for lead (247 companies, 75.3 percent of total) or mercury (47 companies, 14.3 percent of total). Of the 247 companies reported to the Registry for lead, the Occupational Safety and Health Administration (OSHA) inspected 18 of 98 companies (18.4 percent) in the manufacturing sector, but only one of 149 companies (0.6 percent) outside the manufacturing sector. We conclude that the Registry effectively detects companies with heavy metals exposures, and is an especially useful adjunct to OSHA inspections outside the manufacturing sector. (*Am J Public Health* 1990; 80:162–164.)

Introduction

Heavy metals are common contaminants of the occupational environment. Absorption of metals can cause abnormalities of biochemical, cellular, and physiological function, as well as disease or death.[1] Occupationally related diseases are under-reported,[2] and surveillance may detect industries and companies with excessive exposures.[3–5] Methods of surveillance for occupational heavy metals exposure include Occupational Safety and Health Administration (OSHA) inspections for violations of the federal lead standard,[5,6] workers' compensation claims,[7] and the National Occupational Hazard Survey.[8,9]

In New York State, the two most useful sources of biological monitoring or industrial hygiene data are: 1) the New York State Heavy Metals Registry, a case registry of persons with elevated heavy metals levels in blood or urine, and 2) results of OSHA inspections for violations of the federal lead standard. The purposes of this paper are to present the methods and results of the Heavy Metals Registry during its first five years of operation (1982–86), and to determine whether companies reported to the Registry for lead have been inspected by OSHA for violations of the federal lead standard.

Methods

Sections 22.6 and 22.7 of the New York State Sanitary Code require that clinical laboratories, hospitals, and physicians report persons with heavy metals absorption to the state health department. The health department provides reporting forms which include name and residence, age, sex, heavy metals concentrations, report source (i.e., analytic laboratory, company, hospital, or physician), and private physician. Confidentiality is protected by a public health law which restricts use of the data to scientific or medical research and renders the information inadmissible as legal evidence.

Cases are defined from the reporting form as state residents 18 years of age or older with elevated levels of lead in blood (Pb-B $\geq$ 40 μg/dL or 1.93 μmol/L) or urine (Pb-U $\geq$ 80 μg/L), mercury in blood (Hg-B $\geq$ 5 μg/L or 0.02 μmol/L) or urine (Hg-U $\geq$ 20 μg/L) cadmium in blood (Cd-B $\geq$ 10 μg/L or 0.09 μmol/L) or urine (Cd-U $\geq$ 5 μg/24 h), or arsenic in urine (As-U $\geq$ 50 μg/L).[6,10–12] In 1987, the lead reporting levels were lowered to 25 μg/dL blood and 50 μg/L urine.

Cases are interviewed when the first report is received, either by telephone or in person. The interview includes questions on name and address of employer, work history (job titles and workplace exposures), industrial hygiene and exposure monitoring programs, hobbies, medical history, and demographic information. The Standard Industrial Classification (SIC) system of categorizing the employer is used.[13]

Occupational exposure is defined from the interview as a positive response to the questions of either working with or being exposed to heavy metals; in addition, if other workers from the same company have been reported to the Registry, the employer is interviewed to determine if the case could be exposed. Nonoccupational exposures include pica in the institutionalized, poisonings, avocational use of firing ranges, and home manufacture of lead shot and sinkers.

Clinical laboratories which analyze lead in state residents must be certified through proficiency testing, whether or not the laboratory is located in the state. Clinical laboratories in addition to those listed on the reporting forms have been found through a state survey of companies which store, use, or discharge toxic chemicals.[14] Employers known to be using heavy metals are interviewed to determine the number of workers using heavy metals, whether workplace air or biological samples are monitored, and which clinical laboratory is used.

Employers of reported cases are offered industrial hygiene consultation. The private physician is contacted when high levels are reported to ensure that information concerning the employer has been received and, if necessary, to assist in contacts with the employer. Companies whose employees have especially high or persistently elevated levels may be investigated by the health department or reported to OSHA.

Results

From 1982–86, 2,862 of the 3,309 cases (86.5 percent) reported to the Registry were interviewed; of these, 2,798 (97.8 percent) provided employer information. The employer could be determined from other sources such as the labora-

TABLE 1—Number of Cases and Companies by Industrial Sector and Metal, New York State Heavy Metals Registry, 1982–86 (occupational exposures only)

Industrial Sector	Number of Cases				Number of Companies			
	Pb	Hg	As	Cd	Pb	Hg	As	Cd
Manufacturing	1241	873	52	22	98	21	3	5
Non-manufacturing	368	127	34	4	149	28	15	4
Total	1609	1000	86	26	247	47	18	9

Pb = lead; Hg = mercury; As = arsenic; Cd = cadmium. Manufacturing sector = SIC major group 20-39; non-manufacturing sector = all other SIC codes (Standard Industrial Classification).[13]

tory report in 375 of the 448 cases (83.7 percent) who were not interviewed; thus, the current employer was known for 3,173 cases (95.9 percent of total). There were no differences in metals levels between cases whose employer could and could not be determined.

A total of 2,739 occupational cases were reported from 328 companies. The cases were predominantly male (92.0 percent) and less than 40 years of age (57.1 percent); all cases were employed at their current company for at least one month. Clinical laboratories (N = 72) reported 88.9 percent of cases. Thirty-three of the clinical laboratories, including the largest reporter, were located outside the state; out-of-state sources reported 53.3 percent of cases.

Table 1 presents the distributions of reports by industrial sector. The predominant reporting was for lead (58.7 percent of cases, 75.3 percent of companies) and mercury (36.5 percent of cases, 14.3 percent of companies). The manufacturing sector (SIC major group 20–39) accounted for 80.4 percent of cases and 39.9 percent of companies. The largest numbers of non-manufacturing sector companies were reported in the service sector (SIC major group 70–89; 58 companies, 23.5 percent of total) and in the construction sector (SIC major group 15–17; 42 companies, 17.0 percent of total).

The four-digit SIC codes of industries with 20 or more cases are presented in Table 2. This criterion is arbitrary and does not imply that significant hazards do not exist in industries with fewer cases. The largest fraction of lead cases was employed in secondary smelting and refining of nonferrous metals; of mercury cases, in the manufacture of alkalies and chlorine. Industrial instrument manufacture was notable for a large number of cases and a high median urinary mercury.

Companies reported to the Registry for lead were com-

TABLE 2—Median and Maximum Heavy Metals Levels in Industries with 20 or More Cases, by Metal and Four-Digit SIC Code, New York State Heavy Metals Registry, 1982–86 (occupational exposures only)

Four-digit SIC Code and Metal	Industry Description	Reported No. of Cases	Metals levels	
			Median	Maximum
Blood Lead			(μg/dL)	(μg/dL)

3861	Photographic equipment and supplies	49	80	524

n.e.c. = not elsewhere classified. SIC = Standard Industrial Classification.[13] Reporting criteria: Blood lead ≥40 μg/dL or 1.93 μmol/L, urinary mercury ≥20 μg/L, urinary arsenic ≥50 μg/L.

pared with those inspected by OSHA from 1980–85 for violations of the federal lead standard. OSHA inspections were focused on the manufacturing sector to a much greater degree than Registry reports: 130 of 157 companies (82.8 percent) inspected by OSHA were in the manufacturing sector, as compared to 98 of 247 companies (39.7 percent) reported to the Registry. OSHA inspected 18 of 98 (18.4 percent) of companies reported to the Registry from the manufacturing sector, but only one of 149 (0.6 percent) companies outside the manufacturing sector.

Discussion

The Registry has several advantages compared to other surveillance methods. It is inexpensive to operate because existing data sources are used. Apart from error in the analysis of samples, there is little uncertainty regarding exposure because cases are defined by increased biological absorption. Clinical laboratory-based reporting eliminates the need to enlist the cooperation and time of individual physicians and health facilities, whose reporting is redundant to the extent that samples are sent to clinical laboratories for analysis.

Perhaps most importantly, surveillance can be carried out in industrial sectors which have a low priority for regulatory agencies and for metals for which no governmental standards exist. OSHA inspections target private companies in the manufacturing sector, larger companies, and industries with previously reported exposures. Of the four heavy metals on which Registry data are collected, a federal standard has been promulgated for lead only.

For most companies, the source of exposure is known. Lead exposure in secondary smelting and refining of nonferrous metals (SIC 3341) and storage battery manufacture (SIC 3691) results from melting of lead alloys and dust exposure during foundry or fabrication work. Alkali and chlorine manufacture workers (SIC 2812) are employed in a chloralkali plant where mercury is used as a cathode in the electrolysis of salt to produce sodium hydroxide and chlorine gas; exposure occurs when the mercury cells are opened for maintenance. Mercury exposure in industrial instrument manufacture (SIC 3823) occurs during manual assembly and fabrication of thermometers. In a small fraction of industries, heavy metals exposures have not been previously documented. The source of exposure is apparent in some, but in others more detailed investigations are necessary.

In summary, the Registry is effective in detecting companies with heavy metals exposures, particularly those outside the manufacturing sector which are not detected by OSHA inspections. Since 1982, heavy metals registries have been established in New Jersey, California, Texas, and Maryland. We recommend adoption of this surveillance method by other state health departments, and evaluation of the feasibility of a national heavy metals absorption registry.

ACKNOWLEDGMENTS

We thank Cornelia Dellenbaugh for comparing Registry reports with OSHA inspections, and Dr. William Stasiuk for encouraging development of the Registry. More detailed information on Registry methods and results can be obtained from the Bureau of Occupational Health, New York State Department of Health, Two University Place, Albany, NY 12237. This study was presented at the 114th Annual Meeting, American Public Health Association, September 22–October 2, 1985, Las Vegas, NV.

Call for Papers: Nursing Research

The West Virginia Nurses' Association is planning a national research symposium—"Vision of Excellence: The Decade of the Nineties"—to be held at Greenbrier Hotel, White Sulphur Springs, WV, November 9–11, 1990. This two-day symposium will cover a wide range of health-related topics. The deadline for abstracts is April 15, 1990. Selected papers will be published in the conference proceedings. For further information, contact Dr. Janet F. Wang, School of Nursing, West Virginia University, Morgantown, WV 26506; telephone: (304) 293-4297.

Lead-Induced Anemia: Dose-Response Relationships and Evidence for a Threshold

JOEL SCHWARTZ, PHD, PHILIP J. LANDRIGAN MD, MSC, EDWARD L. BAKER, JR., MD, MPH, WALTER A. ORENSTEIN, MD, AND IAN H. VON LINDERN, PE, PHD

Abstract: We conducted a cross-sectional epidemiologic study to assess the association between blood lead level and hematocrit in 579 one to five year-old children living near a primary lead smelter in 1974. Blood lead levels ranged from 0.53 to 7.91 μmol/L (11 to 164 μg/dl). To predict hematocrit as a function of blood lead level and age, we derived non-linear regression models and fit percentile curves. We used logistic regression to predict the probability of hematocrit values less than 35 per cent. We found a strong non-linear, dose-response relationship between blood lead level and hematocrit. This relationship was influenced by age, but (in this age group) not by sex; the effect was strongest in youngest children. In one year-olds, the age group most severely affected, the risk of an hematocrit value below 35 percent was 2 percent above background at blood lead levels between 0.97 and 1.88 μmol/L (20 and 39 μg/dl), 18 percent above background at lead levels of 1.93 to 2.85 μmol/L (40 to 59 μg/dl), and 40 percent above background at lead levels of 2.9 μmol/L (60 μg/dl) and greater; background was defined as a blood lead level below 1.88 μmol/L (20 μg/dl). This effect appeared independent of iron deficiency. These findings suggest that blood lead levels close to the currently recommended limit value of 1.21 μmol/L (25 μg/dl) are associated with dose-related depression of hematocrit in young children. (*Am J Public Health* 1990; 80:165–168.)

Introduction

Lead-induced anemia is produced principally by two mechanisms: impairment in heme biosynthesis, and increased rate of red blood cell destruction.[1]

Lead-induced anemia has been reported to occur in children at a blood lead level of 1.93 μmol/L (40 μg/dl).[2*] However, no clear dose-response relationships between blood lead level and hematocrit have been established. Further, almost no data are available to assess whether this relationship extends downward to blood lead levels below 1.93 μmol/L (40 μg/dl), to ascertain the fraction of children with lead-induced anemia at various blood lead levels, or to determine whether there exists a threshold, below which the association is no longer evident.

To assess dose-response relationships between blood lead level and hematocrit, we examined data obtained in 1974 during an epidemiologic study of lead exposure in children living near a lead smelter.[3]

Methods

A cross-sectional prevalence study of lead exposure in children living near a lead ore smelter in Kellogg, Idaho, conducted in August 1974, found blood lead levels of 1.93 μmol/L (40 μg/dl) and above in 285 (41.9 percent) of 919 children. Within 1.6 km of the smelter, 170 (98.8 percent) of 172 children had blood lead levels above 1.93 μmol/L (40 μg/dl), the highest being 7.91 μmol/L (164 μg/dl). Blood lead levels were positively associated with exposures to airborne lead (correlation coefficient, $r = 0.72$; $p < 0.0001$) as well as with exposures to lead in soil ($r = 0.5$; $p < 0.0001$).[4]

Blood samples (drawn in lead-free vacuum tubes) were analyzed for hematocrit by centrifugation and for erythrocyte protoporphyrin (EP) by the method of Granick, *et al.*[5] Samples were analyzed for lead by modified Delves' cup atomic absorption spectrophotometry.[6] These methods have previously been described in detail.[3]

A total of 1,058 children, ages 1 to 9 years, were identified for whom data on both blood lead and hematocrit were available. In the present analysis, we focus on the 579 children in the age group 1 to 5 years, since children in this age range appear most sensitive to the hematotoxic effects of lead.

Anemia has been defined variously, with the lower bound of the normal range of hematocrit values in young children varying from 33 to 35 per cent.[7–10] We defined anemia as an hematocrit value less than 35 percent. To assess the relation between blood lead level and hematocrit in children using this definition, we fit logistic regressions, which predict the probability of anemia at different age, sex and blood lead levels.[11]

Initial examination of a raw scatter plot of hematocrit versus blood lead level showed a non-linear dose-response relationship. There was little variation in hematocrit at low blood lead levels and a negative relation with lead at higher levels.

Rather than fitting this relationship directly in a non-linear parametric regression, which imposes an explicit functional form on the data, we employed non-linear smoothing techniques developed for robust graphical analysis.[12,13]

Results

The smoothed plot of the data follows a logistic-shaped curve (Figure 1), which is relatively flat at blood lead levels below 0.97 μmol/L, becomes increasingly steep as blood lead levels rise, and, at very high lead levels, flattens again. This curve can be represented by the logistic function:

$$Hct = A/(1 + EXP(B_o + B_1*lead + B_2*age)) + C \qquad (1)$$

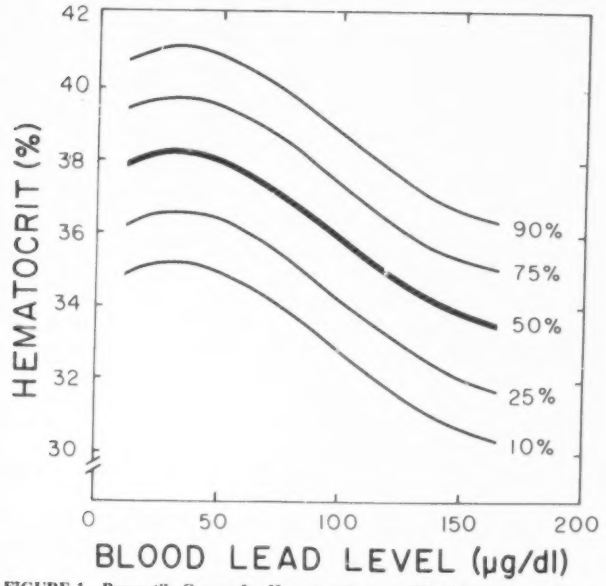

FIGURE 1—Percentile Curves for Hematocrit versus Blood Lead Level in 1–5 Year Old Children, Northern Idaho, 1974

The logistic regression analysis showed a strong association between elevation of blood lead level and the probability of anemia (regression coefficient = 0.3083; (SE = 0.0061). Year of age was also a significant predictor of low hematocrit (coefficient = −0.3831; SE 0.1134). In this age group, sex was not a predictor of anemia. The predicted probability of anemia in relation to blood lead level is plotted graphically for each year of age in Figure 2.

To illustrate the fit of the predicted curve to the actual data, Figure 3 shows both the predicted curve and actual points for the mean proportion of children with anemia for each interval of 0.48 µmol/L (10 µg/dl) in blood lead level after controlling for age. The highest point represents the mean for the five children with blood lead levels greater than 5.79 µmol/L (120 µg/dl).

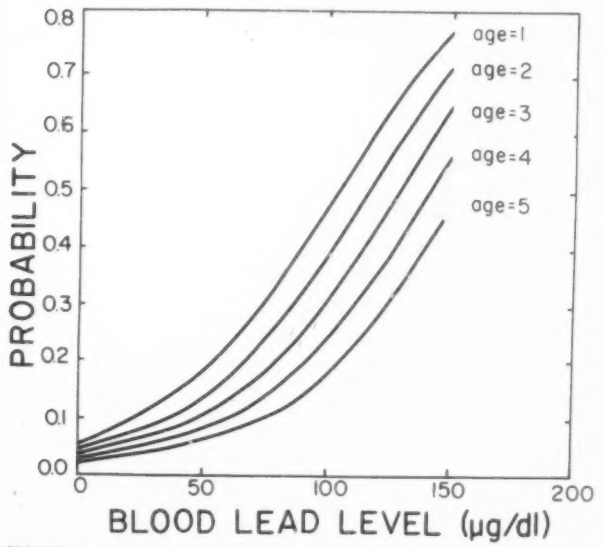

FIGURE 2—Predicted Probability of Hematocrit <35% by Age and Blood Lead Level in 1–5 Year Old Children, Northern Idaho, 1974

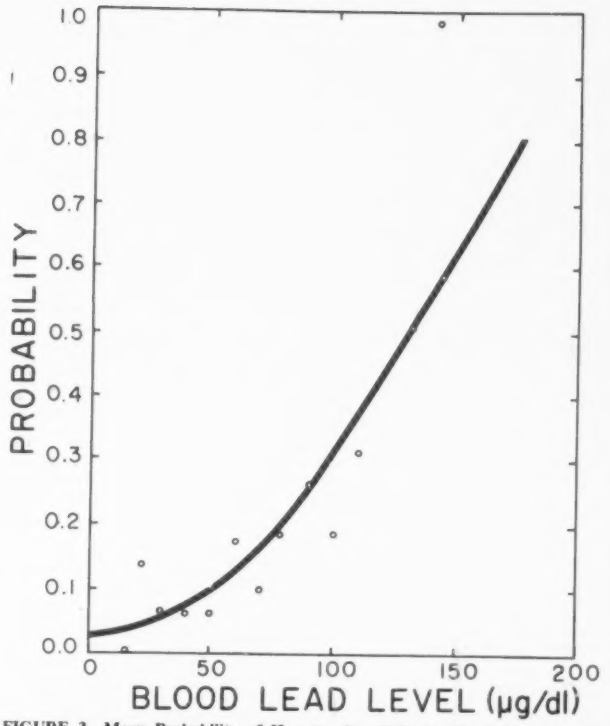

FIGURE 3—Mean Probability of Hematocrit <35% by Blood Lead Level, Northern Idaho, 1974 (This line is the fitted logistic curve for the probability of hematocrit <35% after adjusting, by regression, to the mean age)

Since Figure 2 suggests that the increased risk of depressed hematocrit begins at lower blood lead levels in one year-olds than in five year-olds, we calculated the mean proportion of children in each year of age with an hematocrit below 35 percent at various blood lead levels (Table 1). To compensate for the reduced sample size, we used increments of 0.97 µmol/L (20 µg/dl) in blood lead levels. While the sample size was too small to draw strong conclusions, the results were concordant with the regression analysis (Table 1). In one year-old children the probability of anemia was 0 percent at blood lead levels below 0.97 µmol/L (20 µg/dl), 2 percent at levels between 0.97 and 1.93 µmol/L (20 and 39 µg/dl), 18 percent at levels between 1.93 and 2.90 µmol/L (40 and 60 µg/dl), and 40 percent at blood lead levels above 2.90 µmol/L (60 µg/dl).

We also examined actual hematocrit values rather than proportion anemic. In Figure 1, the 20th, 25th, 75th, and 90th percentile curves reflect the broad variation in hematocrit levels due to age, iron deficiency and other factors. Percentile curves were estimated by confirming the homoscedasticity of the residuals from the smooth curve and then estimating their standard deviation from their interquartile range; percentiles were then calculated from the standard deviation. Table 2 presents the results of nonlinear regression of hematocrit on age and on blood lead level.

Figure 4 plots predicted hematocrit levels by age and blood lead level. Again, it shows the strong effect of age on hematocrit in young children, and demonstrates the interrelationship between age and blood lead level.

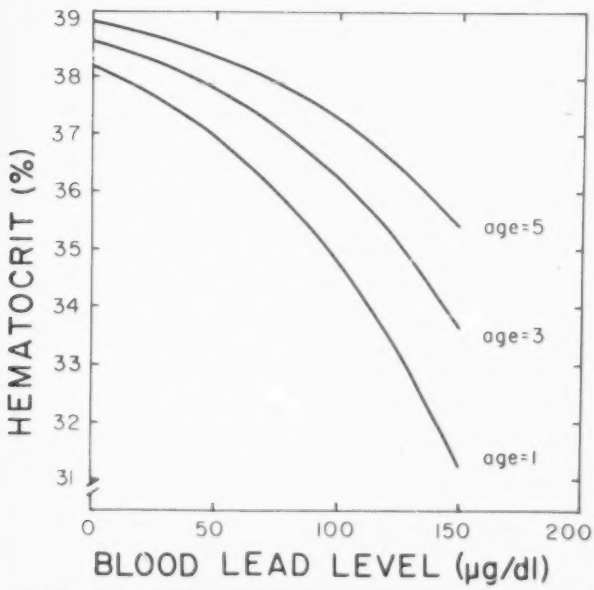

FIGURE 4—Predicted Hematocrit Value versus Blood Lead Level, by Age, in 1–5 Year Old Children, Northern Idaho, 1974

Discussion

The results of this study show a strongly negative, non-linear dose-response relationship between blood lead level and hematocrit in children, strongest in the youngest children. Although there is variability among children in the effect of lead on hematocrit, the data from this study suggest that lead-induced anemia is a biologically and clinically important consequence of lead absorption, even at low levels of exposure.

Iron deficiency may have accounted for some of the observed effect of lead on hematocrit since the effects of lead and iron deficiency on hematocrit have been shown to be strongly interactive.[14] Although data on the iron status of the children in our study were not obtained, the strong correlation between low socioeconomic status, elevated lead levels, and iron deficiency typically seen in urban populations did not exist in our study population. In our population, blood lead levels were determined principally by distance from the smelter and were not correlated with socioeconomic status,[3,4] hence lead exposure and iron deficiency were probably not correlated in these data.

The smoothed dose-response curve of hematocrit versus blood lead level (Figure 1) shows a slight, paradoxical increase in hematocrit at low blood lead levels, followed by a decrease, whose slope steepens until blood lead levels reach 4.83 μmol/L (100 μg/dl) and then subsequently flattens out again. The slight increase in hematocrit observed at the lowest blood lead levels may be artifactual. Since children with lowest blood lead levels came from a rural valley distant from the smelter town, with low family income and socioeconomic status, nutritional deficiency may have been more common there and account for the observed results. Alternatively, the effect may be due to differential partitioning of lead among the soft tissues of the body. At equilibrium, the fraction of lead stored in any body compartment will be proportional to the size of the compartment. At body burdens too low for lead to affect hemoglobin levels, higher hemoglobin levels could increase the fraction of lead stored in red blood cells thus causing the positive correlation seen here.

These data imply that there is no margin of safety between the threshold blood lead level at which lead begins to cause depression of hematocrit in young children and the blood lead level currently considered by the Centers for Disease Control to represent the upper limit of acceptability—1.21 μmol/L (25 μg/dl)[15] These findings complement other data showing deleterious effects of lead on heme synthesis of blood lead levels of 0.48 to 0.97 μmol/L (10–20 μg/dl), on vitamin D metabolism at blood lead levels below 1.21 μmol/L (25 μg/dl), on peripheral nerve conduction velocity at 0.97 to 1.45 μmol/L (20 to 30 μg/dl) and on cognitive function at 0.72 to 0.97 μmol/L (15 to 20 μg/dl).[16–22] Taken together, these findings suggest that the current recommendation on the acceptable upper limit for blood lead level in children requires reexamination.

Call for Applications: Minority Medical Faculty Development Program 1990

The Robert Wood Johnson Foundation's Minority Medical Faculty Development Program offers four-year, postdoctoral research fellowships to minority physicians who have demonstrated superior academic and clinical skills and who are committed to careers in academic medicine and biomedical research. Each of the Fellows selected (up to eight) will receive an annual stipend of up to $50,000, complemented by a $25,000 annual grant toward support of research activities. Each Fellow will study and conduct research under the supervision of a senior faculty member located at an academic center of biomedical research noted for the training of young faculty and pursuing lines of investigation that are of interest to the Fellow. Priority will be given to basic research. It is expected that Fellows will be spending no less than 70 percent of their time in pursuit of research activities.

The Minority Medical Faculty Development Program seeks to increase the number of minority faculty who can encourage and foster the development of succeeding classes of minority physicians. At present, only 1,281 (3.2 percent) of the nation's 40,136 full-time medical faculty members are minorities.

Foundation support for the four-year fellowships will be provided initially for *two years*, with funding for the third and fourth years dependent upon review and recommendation by the National Advisory Committee. The fourth year of support may be used to assist the Fellow in his or her first year as a full-time medical faculty member.

To be eligible, applicants must be minority physicians who are US citizens, have excelled in their education, are now completing or will have completed formal clinical training (internship, residency, or clinical fellowship), and are committed to academic careers.

April 2, 1990—Deadline for request of application materials.

By April 30, 1990—Receipt of completed applications.

July 1990—Interviews with National Advisory Committee and consultants in biomedical research.

December 1990—Official notification of Fellows.

Requests for applications and inquiries should be addressed to: Harold Amos, PhD, Program Director, Minority Medical Faculty Development Program, P.O. Box 446, Brookline, MA 02147. Tel: 617/732-1947.

An Analysis of Occupational Risks for Brain Cancer

Ross C. Brownson, PhD, John S. Reif, DVM, MSc, Jian C. Chang, PhD, and James R. Davis, MS

Abstract: We evaluated the risks of brain cancer in relation to employment history in a case-control study of 312 cases and 1,248 cancer controls. Subjects were identified through the Missouri Cancer Registry for the period 1984 through 1988. Job classification was based on data routinely abstracted from hospital records. Elevated risks were identified for certain white collar occupations: for men employed in engineering, the odds ratio (OR) = 2.1; 95% confidence interval (CI) = 0.4, 10.3; for social science professionals, the OR = 6.1; 95% CI = 1.5, 26.1. Among occupations with potential exposure to occupational carcinogens, increased risks were observed for men employed in agricultural crop production (OR = 1.5; 95% CI = 1.0, 2.4), printing and publishing (OR = 2.8; 95% CI = 1.0, 8.3), and brickmasons and tilesetters (OR = 2.5; 95% CI = 0.5, 11.5). Most of elevated brain cancer risks were due to astrocytic cancers, but the excess among agricultural workers occurred in other cell types. No increase in risk was noted for current cigarette smokers (OR = 0.9; 95% CI = 0.7, 1.5) or ex-smokers (OR = 1.0; 95% CI = 0.7, 1.5). This exploratory study indicates a need for further studies of occupational risks of brain cancer. (*Am J Public Health* 1990; 80:169–172.)

Introduction

Cancer of the brain has been the focus of relatively few epidemiologic studies. Increased risks have been noted for several white collar occupations including accountants,[1] sales managers,[2] engineers,[2,3] teachers,[1] lawyers and judges,[2] and postal clerks.[3] Among occupations with potential carcinogenic exposures on the job, excess brain cancer risk has been suggested for workers employed in the rubber industry,[4,5] polyvinyl chloride production,[6–9] farming,[10–13] electrical industries,[14–16] pharmaceutical production,[17] and production of petroleum and petrochemicals.[18,19] Cigarette smoking has also been linked to brain cancer risk.[20]

Most previous studies of occupation and brain cancer have relied on mortality data, with concomitant potential for misclassification of brain cancer on death certificates.[21] Few previous studies have evaluated differences in occupational risks by histologic type of brain cancer. The current study was based on data from a statewide cancer registry.

Methods

Cases and controls were identified through the Missouri Cancer Registry, maintained by the Missouri Department of Health. The Registry has been collecting data on cancer cases from public and private hospitals since 1972, with reporting mandated by law since 1984.

The case group consisted of White males diagnosed with histologically confirmed brain and other central nervous system cancer (*International Classification of Diseases for Oncology* [ICD-O] codes 191 and 192)[22] between January 1984 and December 1988. Selection was limited to White males due to the small number of non-Whites and the lack of reported occupational diversity among females. The mean age among cases was 54.6 years.

A frequency-matched sample of controls was chosen from all other white male patients diagnosed with cancers in the same time period, excluding cancers of ill-defined or unknown primary sites (ICD-O site codes 195 and 199). For each case, four controls were randomly selected within each of six age strata. The mean age of controls was 55.6 years. The analyses included a total of 312 cases and 1,248 controls. The distribution of cancer sites among controls is shown in Table 1.

Data on occupation and tobacco use are routinely abstracted from the hospital medical record at the time of diagnosis and submitted to the Missouri Cancer Registry as part of cancer incidence reporting. Hospital registrars record information for cancer patients using a standardized protocol and the occupational data are subsequently coded by trained cancer registry specialists using the three-digit 1980 US Census codes.[23] The occupational history reported to the Registry is intended to represent the usual or longest held job of the cancer patient. Smoking history for each patient is characterized according to status (i.e., never, former, or current use) and, among current smokers, according to the number of packs smoked per day.

The present analysis was based on subjects who had codable occupational information (i.e., either occupation or industry or both variables). The remaining subjects had no occupational information or noninformative job titles such as "retired." Duration of employment was only occasionally recorded and not used in these analyses. Of the initially eligible subjects, 34 percent of potential cases and 38 percent of potential controls were excluded due to missing occupational information.

The odds ratio (OR) was the measure of association between occupation and brain cancer. Gart's method[24] was used to calculate maximum likelihood estimates of the OR

TABLE 1—Distribution of Cancer Sites in Control Group, Missouri, 1984–88

Site of Cancer	Number	Percent
Lip, oral cavity, and pharynx	57	5

Dr. Reif is with the Department of Environmental Health at Colorado State University, Fort Collins; Dr. Chang is with the Missouri Cancer Registry, Missouri Department of Health, Columbia; Mr. Davis is with the Bureau of Smoking, Tobacco, and Cancer, Missouri Department of Health, Columbia. This paper, submitted to the Journal May 8, 1989, was revised and accepted for publication August 18, 1989.

and corresponding 95 percent confidence intervals (CI). For each occupation and industry with two or more cases, age- and smoking-adjusted ORs were computed. The reference category consisted of all persons not in the occupation of interest.

Separate analyses were conducted for the astrocytic series (ICD-O morphology codes 93803, 93823, 94003-94413) and for "other" cell types of brain cancer. The astrocytic series was comprised primarily of unspecified astrocytomas (31 percent), unspecified glioblastomas (51 percent), and anaplastic astrocytomas (7 percent). "Other" cell types included oligodendrogliomas (31 percent), unspecified cell types (20 percent), and unspecified ependymomas (14 percent). All controls were used in each cell type analysis.

For analyses by smoking history, we excluded controls with cancers of smoking-related sites (lip, oral cavity, esophagus, larynx, lung, and bladder—ICD-O site codes 140-141, 143-145, 150, 161, 162, and 188).

Results

Risk of brain cancer according to industry of employment is shown in Table 2. Men employed in agricultural crop production had a moderately elevated risk (OR = 1.5; 95% CI = 1.0, 2.4). An OR of 2.8 (95% CI = 1.0, 8.3) was observed for workers in printing and publishing. Several other industries were associated with risks of 2.0 or greater, although estimates were based on small numbers. These included men employed in miscellaneous repair services (OR = 2.6; 95% CI = 0.5, 13.0), engineering services (OR = 2.1; 95% CI = 0.4, 10.3), and justice, public order, and safety (OR = 2.1; 95% CI = 0.9, 4.8).

As shown in Table 3, excess risks were found for social science professionals (OR = 6.1; 95% CI = 1.5, 26.1) and for police and fire protection services (OR = 2.2; 95% CI = 1.0, 4.7). The excess among police and fire protection services included an OR of 2.9 (95% CI = 0.8, 11.0) for police and detectives and an OR of 2.0 (95% CI = 0.4, 9.6) for firefighters. An OR of 2.5 (95% CI = 0.5, 11.5) was observed for brickmasons and tilesetters, although there were only three cases in that job category.

Evaluation of risks according to histologic type of brain cancer showed that the elevated risk in agricultural workers was confined to "other" cell types (OR = 5.3; 95% CI = 1.9, 14.3). The elevated overall risk for workers in printing and publishing was equally distributed between astrocytic and "other" cell types. Elevated risks of astrocytomas were observed for automobile repair work (OR = 1.9; 95% CI = 1.0, 4.1) and justice, public order, and safety (OR = 2.4; 95% CI = 1.0, 5.6).

Social science professionals showed elevated risks for both astrocytomas (OR = 4.7; 95% CI = 1.0, 22.9) and "other" cell types (OR = 19.0; 95% CI = 2.1, 145.6). The

*Odds ratios are reported for job categories that contained two or more cases.

excess risk among police and fire protection workers was confined to the astrocytic cell series (OR = 2.3; 95% CI = 1.0, 5.1). Farmers had an increased risk for "other" cell types (OR = 3.7; 95% CI = 1.4, 9.8). Machinists had an OR of 1.8 (95% CI = 0.6, 5.2) for astrocytomas.

There were 33.7 percent current smokers and 19.9 percent ex-smokers among cases, compared with 34.4 percent current smokers and 18.5 percent ex-smokers among controls. Current smokers had an OR of 0.9 (95% CI = 0.7, 1.3) and ex-smokers had an OR of 1.0 (95% CI = 0.7, 1.5).

Discussion

The present study confirmed previously reported occupational associations[2,3,25] between brain cancer risk and employment in certain white collar occupations. These increased risks may be related in part to better access and utilization of medical services and, hence, a greater likelihood of brain cancer diagnosis.[26]

An increased risk of brain cancer among agricultural workers has been reported in a number of recent studies,[10–13,27] although several others have failed to identify such a relationship.[21,28,29] In the current study, the elevated risk among farmers was confined to "other" cell types. Mussico, *et al*,[30] recently found an increased risk of brain gliomas in relation to use of insecticides or fungicides. Animal studies[31] and elevated levels of organochlorine compounds in adipose tissue of glioblastoma patients[32] adds biological plausibility to the hypothesis that agricultural chemical exposure may be partially responsible for the excess risk of brain cancer in farmers.

The increased risk seen in this study among workers in the printing and publishing industry was unexpected, although one previous study[33] suggested an elevated brain cancer risk in commercial pressmen. Since printers are exposed to a variety of chemicals, this relationship deserves further scrutiny.

Several *a priori* suspected high-risk occupations showed indications of elevated risks in our study; however, some of these comparisons were limited by small numbers. For example, we found slight elevations in risk for chemical manufacturers, mechanics and repairers, and precision metal workers such as machinists, all of which have been reportedly previously.[1,25,29,34] We identified an elevated risk of astrocytomas for automobile mechanics, who are potentially exposed to solvents, lubricating oils, and hydrocarbons.[25] Rushton, *et al*,[35] found elevated brain cancer mortality among bus mechanics in the United Kingdom. Our data suggested an increase in risk of astrocytomas for brickmasons and tilesetters. This association was also reported in a death certificate study from Massachusetts.[34]

We found no indication of an increased risk among smokers. This contrasts with a recent study[21] but is consistent with two earlier studies.[36,37]

The current study has several limitations. We relied on occupational information collected in conjunction with cancer incidence reporting. Of the initially eligible study subjects, over one-third had missing occupational information. The Registry obtains job information based on the hospital medical record at the time of diagnosis and some degree of misclassification is likely. A recent study that compared risk factor information contained in the Missouri Cancer Registry record with information obtained by interview found an agreement of 70 percent between Registry-reported occupation and usual occupation reported by interview.[38] In addition, occupational misclassification was apparently random and would therefore bias relative risk estimates toward unity.[39]

We selected controls from other cancer patients recorded on the Registry, with the attendant advantages and disadvantages.[40,41] We compensated for the relation between smoking and other cancers in sub-selection of controls and adjustment in the analyses.

The strengths of our study included greater accuracy in hospital-reported tumor diagnosis, compared with death certificates,[21] and the ability to analyze by histologic type.

This exploratory study suggests leads for future investigations with more information on occupational exposures and other possible confounders.

The Robert Wood Johnson Clinical Scholars Program

The Robert Wood Johnson Clinical Scholars Program—designed to allow young physicians committed to clinical medicine to acquire new skills and training in the non-biological sciences important to medical care systems—offers two years of graduate-level study and research as part of a university-based, post-residency training program. Open to US citizens training in any of the medical/surgical specialty fields, the Clinical Scholars Program is offered at seven sites funded by the Foundation. The participating universities, their program directors, and priority areas for study and research are:

- University of California-Los Angeles, School of Medicine, Robert H. Brook, MD, Director. *Priority areas:* 1) Caring for America's Problem Populations; 2) Maintaining Quality of Care in a Changing Social and Economic Environment.
- University of California-San Francisco, School of Medicine, and Stanford University School of Medicine *(joint program)*, Bernard Lo, MD, UCSF, and Halsted R. Holman, MD, Stanford, Co-Directors. *Priority areas:* 1) Disease Prevention; 2) Chronic Disease Epidemiology and Management.
- University of North Carolina-Chapel Hill, School of Medicine, Gordon H. DeFriese, PhD, and Robert H. Fletcher, MD, Co-Directors. *Priority areas:* 1) Health Promotion and Preventive Health Services; 2) Aging, Disablement and Long-term Care.
- University of Pennsylvania School of Medicine-Philadelphia, Sankey V. Williams, MD, Director. *Priority areas:* 1) Sociocultural and Historical Studies of Health Care; 2) The Economics of Health Care Systems.
- University of Washington School of Medicine-Seattle, Thomas S. Inui, MD, Director. *Priority areas:* 1) The Interface between Medicine and Major Societal Problems; 2) Assuring Equity, Quality, and Ethical Standards of Care for Vulnerable Population Groups.
- Yale University School of Medicine-New Haven, Alvan R. Feinstein, MD, and Ralph I. Horwitz, MD, Co-Directors. *Priority areas:* 1) Societal Health Problems; 2) Strategies for Effective/Efficient Clinical Care.

Twenty first-year Clinical Scholar positions are funded annually by the RWJ Foundation; the Veterans Administration supports six additional positions each year. Support is provided directly to participating universities which, in turn, provide stipends to the Scholars.

Physicians must meet the eligibility requirements and may request application forms from the program director at one of the participating universities or from Jody Poet, Program Assistant, Clinical Scholars Program, RWJ Foundation, PO Box 2316, Princeton, NJ 08543-2316. Tel: 609/452-8701. The application process begins 18 months before successful candidates would begin their term as Clinical Scholars. For further information, contact the Robert Wood Johnson Foundation at the address above, or the program directors at the various schools.

Work-Related Psychosocial Stress and Risk of Preterm, Low Birthweight Delivery

CHARLES J. HOMER, MD, MPH, SHERMAN A. JAMES, PHD, AND EARL SIEGEL, MD, MPH

Abstract: We investigated whether work-related psychologic stress—defined as work characterized by both high psychologic demands and limited control over the response to these demands—increases a woman's risk of delivering a preterm, low birthweight infant.

We studied 786 employed pregnant women included in the National Longitudinal Survey of Labor Market Experience, Youth Cohort (NLSY), a nationally representative sample of 12,686 young adults. Data concerning work status, job title, and other factors affecting pregnancy outcome were obtained from the NLSY. Assessment of job experience was based on job title, using an established catalogue of occupation characteristics.

After accounting for the physical exertion entailed in a job, occupational psychologic stress as measured by job title was not associated with preterm, low birthweight delivery for the sample as a whole (Relative risk = 1.16, 95% confidence interval .45, 2.95). For those women who did not want to remain in the work force, work-related stress increased their risk of experiencing this outcome (RR = 8.1, 95% CI 1.5, 50.2). Personal motivation toward work, as well as the physical effort of work, should be considered in evaluating the impact of a job's psychologic characteristics on pregnancy outcome. (*Am J Public Health* 1990; 80:173–177.)

Introduction

A greater proportion of pregnant American women now work outside the home for pay than ever before.[1] Whether certain types of work adversely influences the outcome of pregnancy therefore has substantial import for maternal and child health.

Although a number of studies have examined the broader question of the influence of life stress on pregnancy outcome,[2] relatively little research exists in the specific area of work-related stress.[3] Fox, *et al*, compared low birthweight and perinatal mortality rates among active duty military women with a control group matched for race and parity. He found both outcomes significantly more frequent among the active duty group.[4] Mamelle, *et al*, also investigated the combined effects of psychological and physical stressors. She found that women with high levels of occupational fatigue—defined as work with a combination of prolonged standing, excessive routine, exposure to vibrating machinery, exposure to cold, heat or chemicals, and lifting—experienced higher risk of preterm delivery.[5] These studies both exhibit major limitations, including inadequate control for confounding factors and, in Mamelle's study, the possibility of recall bias.[6]

We evaluate here the impact of job related psychologic stress on pregnancy outcome for a national sample of *young* mothers.

Methods

Study Design, Population

We included in this study those women in the ongoing National Longitudinal Survey of Labor Market Experience, Youth Cohort (NLSY) who met study criteria.[10] The NLSY consists of a national probability sample of 12,686 youth who ranged in age from 14–21 years when selected in 1979. The survey intentionally oversampled Blacks, Hispanics, and economically disadvantaged Whites. The use of NLSY sample weights in analyses corrects for this oversampling and allows for generalization to the entire US population for this age group. All analyses presented here incorporate sample weights.

Criteria for inclusion in the study population included: female sex, having had a singleton live birth prior to the 1983 interview, and having worked during the most recent pregnancy. Additional technical criteria necessary for including an NLSY respondent in the analyses were availability of a US Census Bureau occupational and industry code for the job held during pregnancy, of job characteristic information for that job code, and of birth outcome data—birthweight and gestation—for the particular pregnancy (see below). Of the initial 12,686 NLSY respondents, 772 women met all criteria (see Appendix).

Pregnancy Outcome and Risk Factors

The survey respondents provided detailed information concerning family background, social, and educational factors, as well as a thorough job history, at the initial interview in 1979. Since that time, the survey youth have answered an extensive in-person questionnaire annually. Women respondents first gave information concerning their reproductive experiences in 1982, retrospectively describing pregnancy experiences in all previous years. The 1983 interview updated this information and included the weight and number of weeks early or late for the most recent live birth. Only the most recent pregnancy was used for these analyses. The NLSY sample diminished less than 5 percent from 1979 through 1983, with little variation among race or sex groupings.[11]

Using the interview data available from 1979 through 1983, we ascertained information concerning many of the factors known or suspected to influence risk of preterm or low birthweight delivery.[2] Specifically, we abstracted information concerning maternal race (Black, Hispanic, other), maternal age at the time of the infant's birth, maternal federal poverty status during the year of infant birth, maximum grade completed by the mother prior to the infant's birth, grade completed by the infant's maternal grandmother as of 1979, maternal marital status at the time of the infant's birth, smoking during pregnancy, alcohol use during pregnancy,

month began prenatal care, height, prepregnancy weight, weight gain during pregnancy, prior induced abortions, prior total pregnancy failures, parity, and prior low birthweight delivery. Fertility and obstetric data were obtained from the 1982 or 1983 interviews; sociodemographic data were obtained in most cases from the interview most closely following the infant's birth.

Job Characteristics Data

The yearly NLSY interview obtains a detailed job history, including stop and start dates for all jobs. The NLSY staff provide a US Census Bureau occupation and industry code for each job worked for 20 hours per week for longer than nine weeks. Through the use of this history, the child's birth date, and the estimated gestation, we identified those jobs held during pregnancy. Job codes were available for some women working at a lesser level of intensity during pregnancy, provided that the woman worked over 20 hours for nine weeks in the same job prior to the pregnancy. We also derived a measure of the intensity of work during pregnancy, which encompassed both the proportion of pregnancy worked and the hours worked per week.

We used the Job Characteristics Scoring System developed by Robert Karasek to determine job control, job demands, and work-related physical exertion.[12] This system is based on analyses of the pooled responses to the three Quality of Employment Surveys of 1969, 1972, 1977 by a large, representative national samples of workers.[13] Karasek and colleagues derived several scales by factor analysis of these survey responses. Scales were developed separately for men and women, and apply to most US Census Code Occupational/Industry codes.

High values for job control reflect both the skill and creativity required to perform a job (skill discretion), as well as the freedom to make decisions about the work (decision authority). The measure is both reliable and valid.[12]

The psychologic workload measure reflects a job's pace and pressure (e.g., job requires working very hard). Although somewhat less reliable, this measure maintains face validity.[12]

The physical exertion measure is based on one question asked in two of the three Quality of Employment Surveys, specifically, "Does your job require lots of physical effort?" The measure has both face and concurrent validity.[12,*]

Attitudes Toward Working

All respondents were asked in 1979 and 1982 about their aspirations at age 35 ("What would you like to be doing at age 35?": same job, different job, or having a family). If a woman responded "Having a family," she was then asked "would you like to work in addition to having a family?" For these analyses, we classified a woman as uncommitted toward paid work if she responded in the 1979 survey that she did not want to work at age 35 in addition to having a family.

Analysis

We defined each demand/control quadrant by dichotomizing demand and control at the median level of each among NLSY working pregnant women. We considered three related outcome measures:

- preterm, low birthweight, defined as gestation less than 38 weeks and birth weight 2500 grams or under (5.5 pounds);
- low birthweight itself, i.e., birthweight 2500 grams or under;
- birthweight viewed as a continuous value.

We compared the frequency of preterm, low birthweight delivery, frequency of low birthweight, and mean birthweight between women in job characterized by both high demand and low control (n = 262) with women in jobs with all other combinations of demand and control (n = 510).

We dichotomized the physical exertion measure into high and low exertion groups at the median value among NLSY working pregnant women for those analyses incorporating this measure.

We undertook weighted multiple logistic regression to determine the effect of job-related stress on risk of delivering a preterm/low birthweight or low birthweight infant.[14] In these regressions, we adjusted for the potentially confounding influence of: maternal race (Black, Hispanic, other), maternal age, maternal federal poverty status during the year of infant birth, maximum grade completed by infant's mother prior to birth, education of maternal grandmother of 1979, marital status at time of birth, smoking during pregnancy, alcohol use during pregnancy, month began prenatal care, prepregnancy weight, prior induced abortions, prior total pregnancy failures, parity, and prior low birth weight delivery, as well as work-related physical exertion and our measure of work intensity. Similar weighted multiple linear regression analyses were used to determine the effect of exertion on birthweight.

We explored whether the relationship between stressful work and preterm low birthweight varied among those more or less motivated towards work through stratification and through specification of interaction terms (stress × motivation) in the logistic and linear models.

We weighted all analyses with NLSY Sample Weights, which reflect the probability of selection relative to the US population for this age group, and also reflect non-response in any given year.[15] Design effect factors in the NLSY are generally small (less than 2), and are not included in the analyses presented here.**

With the sample size of 780, we could detect a relative risk associated with job stress on the likelihood of delivering a preterm, low birthweight infant of 1.8 with a power of 90 percent.

Results

Sample Attrition and Missing Data

Among women who worked during pregnancy, several differences existed between those women included in the final sample and those excluded due to missing information (either no Census job code or job characteristic score) (Table 1). Most of the exclusions were due to the absence of a job code, in turn due to these women having worked for limited hours. Excluded women were as a group socioeconomically disad-

vantaged relative to other working women, and were more similar to the population of non-working women.

Validation of Measures

The mean birthweight of the infants in the NLSY was 3304 grams. Preterm infants were smaller than term infants, with a mean weight of 2697 grams versus 3389 grams for term infants. Of the 2375 infants included in this study, 8.3 percent weighed less than 2500 grams. Just under 5 percent (4.7 percent) of the NLSY infants were both low birthweight and preterm. NLSY data consistently confirmed those factors well known to influence pregnancy outcome.***

Prominent within the high stress group are jobs of stitchers and sewers in the apparel industry, waiters and food counter workers, nursing aides and orderlies, and cashiers, especially in grocery stores. Low demand, high control work included accountants, mail order salesmen, and bookkeepers. Low demand, low control workers included typists, a variety of cleaning personnel, and household child care workers. High demand, high control occupations included nurses, receptionists, and restaurant managers.†

Impact of Job Characteristics

Women working during pregnancy in jobs characterized by high psychologic demands and low job control were two times as likely to deliver a low birthweight, preterm infant as women working in low exertion jobs (5.1 percent vs 2.6 percent). Similarly, the frequency of low birthweight infants was 1.67 times higher among high stress workers and the mean birthweight of their infants was lower by 78 grams.

Women in high stress jobs were less well educated, had lower prepregnancy weight, and higher smoking frequency***; moreover, almost three-fourths of them in psychologically stressful jobs were also in jobs with high amounts of physical exertion, and physical exertion itself was strongly associated with increased frequency of preterm, low birthweight as well as with the other outcomes (Table 2).

After taking into account the potential confounding effect of job related exertion and other maternal characteristics, we found that the association of job related psychologic stress with preterm, low birthweight, or with any of the other pregnancy outcomes for the sample of women viewed as a whole was no longer important (Table 3).

For those 70 women who stated they did not want to working outside the home after age 35, however, stressful work significantly worsened pregnancy outcomes.

On average their birthweights were almost 500 grams less than infants born to women in less stressful occupations. These differences remained significant when exertion and other maternal factors were considered (Table 4).

Discussion

We found in this study that young women working in jobs characterized by high levels of psychologic demand with little control over the pace and style of response to those demands were somewhat more likely to deliver a preterm, low birthweight infant than women in other jobs, if they were not motivated to continue working.

We considered practically all those factors outside the work experience that are thought to influence pregnancy outcome, and by using an occupational title-based system of job characteristic description, we avoided the possibility of recall bias in determining work stress. The construct of stressful work as being comprised of work with high demands and low control is intellectually appealing; moreover, it, together with the specific instrument used in this study, has been supported in the field of cardiovascular research.[9,16,17]

Despite these strengths, this study does present potential drawbacks in a number of areas. These areas include the nature of the study population, the characteristics of the measures of occupational stress and motivation, and the source of outcome information.

The population used for this study is not representative of all American mothers, but rather represents only those women bearing children during the earlier portion of their potential reproductive years. Such a sample necessarily includes more socioeconomically disadvantaged, unmarried, and minority women than a sample drawn from the entire maternal population. Compared with the women included in the National Family Growth Survey, NLSY mothers are more likely to be Black (21.9 vs 14.1 percent), to have dropped out of high school (29 vs 24.5 percent), and to be unmarried (22.1 vs 17.2 percent).[18] The youthfulness of the sample likely accounts for the somewhat increased preva-

Birthweight		
Does not aspire to work outside home	Low Stress 3561 grams High Stress 3062 grams	mean effect = −295 grams
Does aspire to work outside home	Low Stress 3300 grams High Stress 3262 grams	mean effect = +38 grams

lence of low birthweight relative to concurrent national figures of 6.6–7.6 percent.[2] These demographic characteristics may also explain the decreased frequency of maternal work during pregnancy (66 percent of married primigravidas in the sample worked during pregnancy, compared with contemporary national figures of 85 percent).[1] Nonetheless, while not reflecting the entire age spectrum, the NLSY's emphasis on this younger child-bearing population is important in its own right. Almost half (47 percent) of all births occur to women less than 25 years old.[18]

Concerning the measure of occupational stress, problems may exist relating to both the precision of the measure and its validity among this young population. The use of an occupational title-based system leaves open the possibility that the job experience of the particular women in this study may not be accurately reflected in the job characteristics measure. The indicator of job demand is particularly suspect on this score. Although these measures are unlikely to be biased in any particular direction, use of any imprecise system makes identification of an association difficult.[19]

Moreover, the construct of high demand/low control work as constituting work-related psychologic stress may not fully encompass factors resulting in work stress for young women at early stages of their work careers. Other factors, such as salary, shift worked, flexibility in hours, or availability of maternity and sick leave, may play an equally important role for this population.

The measure of maternal motivation toward work used in this study is not intended to validly predict a woman's employment status at age 35; rather, this measure is used to indicate the woman's current attachment to working. This measure, unfortunately, is not stable even over short periods. Although 9 percent of women in 1979 and 10 percent in 1982 were classified as not intending to remain in paid work, the correlation between these two groups is low (r = .15, kappa = .15).

Finally, all of the outcome measures in this study are based on maternal recall. Although this defect is not found in other studies relating to work and pregnancy outcome, we found the maternal responses very plausible. Mean White and Black birthweights in the NLSY sample, for example, are extremely close to the estimates from the National Natality Survey (3374 grams and 3095 grams for White and Black infants, respectively, in the NLSY, compared with 3391 grams and 3099 grams for White and Black infants in the NNS).[20] Moreover, these data support most of the well known associations with birthweight, low birthweights, and prematurity, such as race, smoking, maternal weight gain, and prior pregnancy experience.

Assuming that our findings are not simply accounted for by these methodologic limitations, why should the impact of high demand/low control work be so strong among women not intending to remain in the paid work force? We can speculate that such women may feel compelled to work, resent it, and that a demanding and restrictive job provides the "last straw." Conversely the over arching desire to remain a part of the gainfully employed population may limit the influence of high demand/low control work on the majority of women who are motivated to remain workers.

Maternal work during pregnancy is likely to be a balance between helpful aspects, such as financial remuneration and social contact, and harmful components. This study sought to determine whether work-related psychosocial stress is one of these harmful aspects. We found that for those relatively few women not desiring to remain in the paid work force, jobs characterized by high demand/low control were independently associated with adverse pregnancy outcome. This finding, based on small numbers, must be considered preliminary pending confirmation in larger studies.

For the remainder of working women, high demand/low control work did not seem to influence the outcomes examined. Due to the limitations in the measures used, however, this study does not preclude an important role for work-related psychologic factors in influencing the outcome of pregnancy for these women. Further research is necessary to clarify which aspects of work are stressful for young women, how these interact with the woman's motivation to work, and how these factors together may influence pregnancy outcome.

APPENDIX

Derivation of Study Sample from National Longitudinal Survey of Youth

12,686	youth in initial sample	Excluded from study:	
	↓	6,398	Men
6,288	Women		
	↓	3,913	Childless as of 1983 interview
2,375	Delivered a child before 1983 interview		
	↓	1,328	Did not work during most recent pregnancy
1,047	Worked during most recent pregnancy		
	↓	207	Working pregnant women did not have job code assigned
840	Working pregnant women had jobs assigned census code		
	↓	54	Women with job codes not matched to Job Characteristics Scoring System
786	Women with job codes matched to Job Characteristics Scoring System		
	↓	14	Women not reporting precise birthweight*
772	Women with job data recalling precise birthweight of most recent birth		

*12 of these women do report whether their infant weighed more or less than 5.5 pounds.

Qualitative Health Research Conference: Call for Abstracts

An international, interdisciplinary conference is being planned for next year to explore issues and developments in qualitative methods and to examine the latest qualitative health research. The conference will be held February 22–23, 1991 at West Edmonton Mall, Edmonton, Alberta, Canada.

Interested researchers are invited to submit abstracts, not to exceed 150 words, for consideration. Send three copies of the abstract—including author(s) name(s), address, institutional affiliation, telephone and fax numbers—by April 19, 1990 to: Janice M. Morse, RN, PhD, Professor and National Health Research Scholar, Faculty of Nursing, CSB 3-120, University of Alberta, Edmonton, Alberta, Canada T6G 2G3. Dr. Morse is also the contact for further information.

Effects of Workplace Smoking Bans on Cigarette Consumption

Ron Borland, PhD, Simon Chapman, PhD, Neville Owen, PhD, and David Hill, PhD

Abstract: A sample of staff working in the Australian Public Service (n = 2113) were surveyed two to four weeks before a mandated total ban on workplace smoking was introduced, and again five to six months later. Among the 391 smokers on whom complete data were available, the workplace smoking bans were associated with reduced rates of smoking, particularly among heavier smokers where the reduction in consumption was over 25 percent. (*Am J Public Health* 1990; 80:178–180.)

Introduction

The evidence for effects of workplace bans on smoking cessation is mixed[1–5]; the reduction in prevalence may be no greater than the spontaneous rate of smoking cessation. Three studies which investigated consumption in continuing smokers, however, found evidence of reductions.[1,3,5]

We examined the impact on smoking behavior of the introduction of a workplace smoking ban in the Australian Public Service, Australia's largest employer group, with over 170,000 employees. The introduction of the ban was announced over a year before its implementation deadline and was followed by publicity, pre-deadline phasing in of restrictions at some worksites, and availability of programs to help smokers stop smoking or to control their consumption. This paper reports evidence of changes in smoking behavior in a longitudinal sample of smokers from work settings with varying levels of restrictions on smoking prior to the mandated ban.

Method

A total of 2,113 employees of the Australian Public Service (from six Departments spread across three cities and 44 locations) was surveyed two to four weeks before the deadline for implementation of the ban, and again five to six months after its introduction. There were 4,215 respondents to the initial survey (a 79 percent return rate). However, 26.3 percent did not include their names on the initial questionnaire and another 11.5 percent had left the public service or were on extended leave, leaving 2,623 whom we attempted to recontact. A total of 2,169 matched surveys were returned (a return rate of 83 percent). However, 56 of these were not usable, leaving the final sample of 2,113.

Preliminary analyses revealed that those who completed both surveys were less likely at the pre-test to have been smokers (22.7 percent) compared to 27.6 percent for those who completed the initial survey only. There were slightly more males in the final sample (55 percent) compared to the initial sample (51 percent), but there was no difference in mean age or in overall daily cigarette consumption.

To explore the effects of the ban on workday cigarette consumption, only the 391 smokers who reported being smokers at both surveys were considered. Excluded from this group were 39 occasional smokers who reported in the initial survey that they did not smoke on workdays and five who did not provide consumption estimates.

The initial questionnaire, completed two to four weeks before the deadline for the introduction of the ban, dealt with smoking status, the extent of current restrictions in their workplace, and the manner in which any existing restrictions were brought about. Smokers were asked to estimate the number of cigarettes they usually smoked on both work and non-work days, and to recall the number of cigarettes they smoked in the previous 24 hours, divided into seven time periods (before work, while working indoors, while working outdoors, during coffee breaks, at lunch time, in the hour immediately after work, and in the rest of the evening). They were also asked about their attitudes to smoking and to smoking bans, but these data are reported elsewhere.[6] A similar questionnaire was administered at follow-up five to six months later.

Results

Of the matched sample of 2113, 492 (or 23.3 percent) were current smokers at the time of the initial survey and 471 (or 22.3 percent) were smoking at follow-up, a reduction of 21 smokers. Fifty-seven smokers at the time of the initial survey were not smoking at follow-up, and 36 previous non-smokers reported smoking. This 1 percent reduction in prevalence over the six month period is about the estimated yearly reduction in prevalence of smoking for Australians.[7] Of those who stopped, 58 percent had done so more than four months before completing the follow-up questionnaire, i.e., closely following the introduction of the ban.

To study the effects of pre-deadline restrictions on consumption, restrictions were divided into those where the person could smoke at their work station (43 percent of respondents), and those where they should not (57 percent). As can be seen from Table 1, the pre-deadline daily consumption difference between those who reported that smoking at their work station was not permitted and those where it was permitted was 4.5 cigarettes per day. Table 1 also shows that the mean reduction in smoking following the ban was 5.2 cigarettes where there had been no pre-deadline work station restrictions, and 1.9 cigarettes where there were such restrictions. This smaller reduction in the latter group should be seen in the light of their lower pre-deadline consumption.

To further explore the consumption reduction in respondents for whom there had been no restrictions prior to the mandated ban, levels of reported usual workday consumption before the ban were divided into three categories (light, moderate, and heavy) and the change from reported pre-ban workday consumption to post-ban consumption organized by usual pre-ban consumption (Figure 1). While light smokers did not change consumption, moderate smokers reduced by an average of 5.8 cigarettes per day (29.1 percent) and heavy smokers reduced by 7.9 cigarettes (26.6 percent).

TABLE 1—Mean Daily Cigarette Consumption before and Six Months after the Workplace Smoking Ban was Introduced, According to Restrictions Previously Imposed

Time of Survey	Pre-ban Smoking Restrictions: Banned at Work Station (n = 221)	Pre-ban Smoking Restrictions: Not Banned at Work Station (n = 170)	Difference (between subjects effect)
Before ban	16.01	20.54	4.53 (2.45, 6.61)
After ban	14.16	15.36	1.20 (−0.55, 2.95)
Before-after difference (within subjects effect)	1.85 (1.00, 2.70)	5.18 (3.94, 6.42)	

NB: 95% confidence intervals in parentheses.

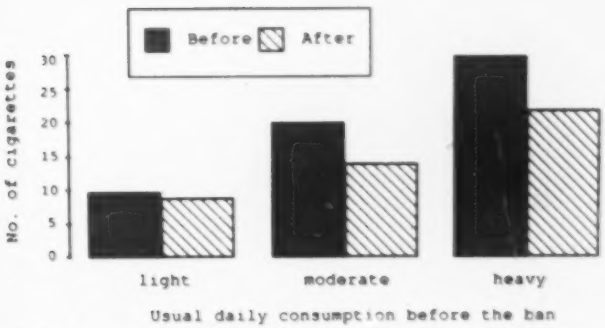

FIGURE 1—Mean Cigarettes Smoked per Day before and after the Ban among Previously Light, Moderate and Heavy Smokers
Light = 1–14 cigarettes/day
Moderate = 15–24 cigarettes/day
Heavy = 25 or more cigarettes/day

As can be seen from Table 2, smokers reduced their average cigarette consumption while working inside by 7.0 cigarettes per day. This was partly compensated for by average increases of 0.7 of a cigarette smoked outside during working hours, and of less than half a cigarette both before work and in the hour after work. The pattern of change was generally consistent for the three smoker categories, except that heavy smokers tended to smoke more outside while working, and the light smokers showed evidence of compensation in the "rest of the evening."

Discussion

Although some smokers may have used the ban's onset and/or the increased availability of smoking cessation resources as stimuli to stop, overall prevalence in the sample changed very little; it is not clear that this resulted in increased rates of smoking cessation compared with normal community rates. The introduction of the workplace smoking ban was associated with reduced levels of cigarette consumption, however. Small increases in rates of smoking outside of the work environment did not compensate for the enforced reduction. Comparison of smoking behavior under two prior levels of restriction on smoking corroborate the evidence that workplace smoking bans are associated with reduced overall levels of smoking, as do data, not reported here,* which showed similar drops in consumption among a small sample who completed 24-hour smoking diaries both before and after the ban.

Relatively little compensatory smoking occurred, and there is no evidence of greater compensation in heavier smokers, who are presumably the most addicted. The fact that smokers did not smoke more at coffee and lunch breaks suggests that the inconvenience of leaving the workplace to smoke was a sufficient obstacle to increased consumption. However, because we did not assess blood nicotine or cotinine levels directly, and did not ask for reports of puff topography, it is not possible for us to show that compensatory changes in puff topography did not occur. Smokers could have increased puff frequency, depth of inhalation, or amount smoked as compensatory mechanisms. However, the environmental restraints imposed by a workplace smoking ban do not favor compensation by changed smoking topography because they reduce opportunities to space cigarettes throughout the day, and compensatory smoking patterns

TABLE 2—Mean Changes in Cigarette Consumption by Usual Smoking Level Reported in the Initial Survey for Those Who Could Smoke at the Work Stations at that Time, Broken Down by Time of Day

	Pre-testing smoking level: Light n = 48	Moderate n = 62	Heavy n = 60	Total n = 170
Before work	0.17 (−0.11, 0.45)	0.31 (0.07, 0.55)	0.80 (0.38, 1.22)	0.44 (0.25, 0.63)
Coffee breaks	−0.04 (−0.44, 0.36)	−0.16 (−0.60, 0.28)	0.07 (−0.42, 0.56)	0.05 (−0.20, 0.30)
Working inside	−2.83 (−3.60, −2.07)	−6.42 (−7.58, −5.26)	−10.97 (−12.79, −9.15)	−7.01 (−7.93, −6.09)
Working outside	0.46 (0.10, 0.82)	0.24 (−0.33, 0.81)	1.37 (0.50, 2.24)	0.70 (0.32, 1.08)
Lunch	0.38 (0.08, 0.67)	−0.13 (−0.37, 0.11)	0.13 (−0.33, 0.60)	0.11 (−0.09, 0.31)
Hour after work	0.46 (0.15, 0.77)	0.31 (0.01, 0.61)	0.55 (0.21, 0.89)	0.44 (0.62, 0.26)
Rest of evening	0.48 (−0.46, 1.42)	0.05 (−0.84, 0.93)	0.13 (−1.18, 1.44)	0.20 (−0.41, 0.81)
Total	0.94 (−2.51, 0.63)	−5.81 (−7.32, −4.30)	−7.9 (−10.62, −5.21)	−5.18 (−6.41, −3.95)

NB: 95% confidence intervals in parentheses.

would result in increased exposure, primarily in the evening when most cigarettes are already reported to be consumed. Nevertheless, if there were compensatory changes, then inferences about the benefits of the reduced consumption would be weakened.

Heavy smokers appear to benefit most from a workplace ban. As heavy smokers typically find smoking cessation most difficult,[8] workplace smoking bans may provide a means by which they can reduce their consumption to less dangerous levels. Although controlled smoking has not been shown to be a generally sustainable strategy under normal conditions,[9] the imposition of environmental restrictions may make long-term controlled smoking more viable in itself, and a useful way station for those who would eventually like to stop smoking completely.

To estimate the impact the ban may have on overall cigarette consumption, we extrapolated our results to the entire Australian Public Service. We estimate that 24.7 percent of 170,000 public servants or about 42,000 are smokers. Taking the estimate of reduced consumption of 5.2 cigarettes a day from the main sample in Table 1, and assuming 240 work days per year, the resultant reduction in cigarette consumption is about 52 million cigarettes. At the current cost of about 10 cents (Australian) for a cigarette, this represents a loss of $5.2 million a year in retail tobacco sales to staff of the Australian Public Service alone. The public health benefits of these restrictions seem clear, but it is also evident what is motivating the tobacco companies to oppose them.

NICHD Funds Two Research Centers on Learning Disabilities

The National Institute of Child Health and Human Development (NICHD) has announced the establishment of the first two US research centers to combine the biomedical and behavioral sciences to focus specifically on learning disabilities. One of the new centers, headed by Dr. Bennett Shaywitz, will be at Yale University in New Haven, CT; the other, headed by Dr. Martha Bridge Denckla, will be located at Johns Hopkins University in Baltimore, MD. Support for the two centers totals approximately $1.5 million, with $550,000 going to Yale, and almost $1 million to Johns Hopkins.

The centers were established in response to the recommendations of the Interagency Committee on Learning Disabilities (ICLD), which was established by the Health Research Extension Act of 1985 to review proposals for research programs and facilities related to learning disabilities in children. The US Department of Education (1987) reports that 4.73 percent of all school-aged children (representing almost 1.9 million children) receive special education services for learning disabilities.

The Yale Center will include three projects: attention and conduct disorders in children and their interrelationships; attentional aspects of cognition; and a study of the distribution, types, and stability of reading, arithmetic and attention problems in a representative sample of children selected at age five and followed for two years.

The Johns Hopkins Center proposes a multidisciplinary program; through the convergence of biomedicine and education, investigators hope to discover how and why children develop learning disabilities. The program will include neurologists, psychiatrists, geneticists, statisticians, psychologists, special educators, and communication specialists.

The investigators plan to use molecular genetics technology and magnetic resonance imaging (MRI) to study the origins of learning disorders. The research will focus on the psychological processes related to brain development as well as the effects of educational intervention. To gain a better understanding of Attention-Deficit-Hyperactivity-Disorder, investigators will study the visual, spatial and motor deficits in families with a history of known genetic defects. Methodological approaches will include neuropsychological analysis and MRI correlates of intervention-resistant reading disabilities.

Precision and Accuracy of a Portable Blood Analyzer System during Cholesterol Screening

PHILIP GREENLAND, MD, NANCY L. BOWLEY, RN, CAROL A. FRENCH, BS, BARBARA MEIKLEJOHN, MS, SALVATORE GAGLIANO, BS, AND CHARLES E. SPARKS, MD

Abstract: The precision and accuracy of two Kodak Ektachem DT-60 portable blood analyzers were assessed in a model (research) cholesterol screening program in Rochester, New York. Between June and October 1987, a total of 8,573 people underwent a cholesterol screening held in a movable trailer. A wide variety of temperature, humidity, and other potentially adverse conditions were encountered during the screening period. Between-run coefficients of variation ranged from 1.9 percent to 4.8 percent per month; average bias compared to a Reference Laboratory method ranged between +0.2 percent and +2.0 percent. Both precision and accuracy met currently recommended standards for cholesterol testing in the United States. (*Am J Public Health* 1990; 80:181–184.)

Introduction

In 1985, the National Institutes of Health initiated a National Cholesterol Education Program intended to inform health professionals and the general public about the significance of high blood cholesterol levels.[1] It is now recommended that cholesterol testing be performed on all adults in the United States.[2] Interest in blood cholesterol coincides with the recent availability of analytical systems that allow cholesterol concentration to be measured in a matter of minutes with small volumes of whole blood, serum, or plasma. Some of these systems are portable and could facilitate almost-immediate feedback to screening participants. The instruments appear to be highly acceptable to consumers because they avoid venipuncture in favor of fingerstick blood sampling.[3] While found to be reliable when evaluated in physicians' office or laboratory settings, there is little information concerning the portable blood analysis systems over extended time periods under field conditions.[4–6]

A report from the Laboratory Standardization Panel of the National Cholesterol Education Program[7] indicates that well-established clinical laboratories may lack acceptable accuracy in cholesterol measurement. Given the problems that have been noted with major laboratories in cholesterol testing, it is critically important to assess the reliability of the portable testing systems under true field conditions before they are widely recommended for general use in public screenings. We report such an assessment.

Methods

The Rochester, New York Model Cholesterol Screening Program

A model cholesterol screening program funded as a demonstration research project by the National Heart, Lung, and Blood Institute was conducted in the metropolitan Rochester, New York, area during a 13-week period from June to October 1987. Ten grocery stores served as the sites of the cholesterol screenings, and 8,573 screenees participated.

The Analytical System

The Kodak Ektachem DT-60 was evaluated for total cholesterol determinations. Cholesterol measurement on this system utilizes a dry, multilayered, self-contained analysis element coated on a clear polyester support ("slide"). Cholesterol esters are hydrolyzed to cholesterol, which is then oxidized to generate hydrogen peroxide. The hydrogen peroxide oxidizes a leuco dye in a peroxidase-catalyzed reaction to produce a colored compound. Colorimetric measurement by reflectance spectrophotometry provides the basis for the final cholesterol concentration value. A 10 microliter drop of plasma or serum is deposited on the slide by a single-tipped battery-driven pipette and is evenly distributed on the slide by a spreading layer. Once spotted with plasma or serum, the slide is manually advanced into the analyzer for further processing. Assay time is slightly more than five minutes; six samples may be loaded in the analyzer simultaneously, and maximum throughput is about 65 cholesterol slides per hour. Results appear both in a visual display and on a hard copy.

Two DT-60 Analyzers (designated here DT-60A and DT-60B) were purchased from the regular production line. The instruments were operated by a screening team of 20 people who were trained by supervisory personnel. None of the screeners had prior laboratory or chemistry experience.

Training and Prescreening Operation

Screening supervisors learned to operate the instruments during a standard 3 to 4-hour training period conducted by Kodak sales personnel. For each of 10 days prior to the actual screening program, two supervisors prepared the instruments for use and ran four sets of reference materials in pairs, along with actual patient-derived blood samples, twice each day. Thus, each day, each reference sample was run four times on each analyzer. These reference values were compared to target values provided by the manufacturer and were used to establish calibration of each DT-60. Precision data were assessed to determine readiness for actual field operation. The supervisors then trained the screening team, each member receiving 3 to 4 hours of practice and training prior to field operation of the instruments. In the field, the screening team was supervised closely, especially for the first 2 to 3 weeks to avoid technical errors.

Environmental Conditions

Screenings were held in an 8′ × 35′ construction trailer equipped with a room air conditioner. The trailer was not

This paper, submitted to the Journal February 3, 1989, was revised and accepted for publication June 23, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

heated, and no attempt was made to standardize trailer temperature or humidity. The trailer was allowed to simulate the wide variety of temperature and moisture conditions that might be encountered in community screening programs. On one potential screening day in early October, when outside temperatures reached below 10°C, both DT-60 analyzers failed to reach operating temperature, and screenings had to be canceled. No other obvious malfunctions were noted due to environmental conditions in the construction trailer. The instruments were started and shut down anew each day.

Precision

Instruments were calibrated using Kodak supplies as described by the manufacturer for the DT-60. At the beginning of each day's operation, a series of three separate commercially prepared reference samples was run on both DT-60 Analyzers to assess continued evidence of calibration. Screenee samples were analyzed either on DT-60A or DT-60B, whichever was ready first. Samples were run in duplicate when the first determination for total cholesterol was <3.35 mmol/L or >7.25 mmol/L. Reference material values were "rejected" when a reference value was greater than two standard deviations from the target value, as determined during the prescreening period on replicates of reference materials. The "rejected" specimen was repeated and, if still out of range, the operations protocol specified discontinuation of analyses until the instrument was recalibrated. After analysis of 10 screening samples on a given instrument, a low-range reference sample was run. Following 10 more screening samples, an intermediate-range reference sample was run, and following an additional 10 screening samples, a high-range reference sample was run. Thus, after 30 screenee samples, a series of three reference samples was completed. This procedure was repeated throughout a day's run on both DT-60 instruments. Between-run precision only is reported here.

Accuracy

Accuracy of the DT-60 instruments was assessed using patient samples (venous serum) obtained from hospitalized patients. Fresh samples were split and run on DT-60A, DT-60B, and by the Abell-Kendall Manual Reference Method in a CDC-standardized laboratory. Paired runs were performed three times during the screening program, approximately six weeks apart. Sixty-eight samples were tested on all three instruments/methods. Samples were run on the DT-60s by usual screening team members at the end of the day's screening work.

Results

The precision data during the 10 days of practice (or training) prior to actual screening in the field are shown in Table 1. While coefficients of variation (CV) for the entire 10-day period, for each instrument (DT-60A and DT-60B), were overall quite acceptable, especially in the clinically important values above 5.15 mmol/L, accuracy of the instruments was less acceptable. For example, the CV for the reference sample target of 7.00 mmol/L was 2.22 percent for DT-60A and 2.59 percent for DT-60B over the 10 days. However, mean values on both instruments fell below target values throughout the entire range of reference samples studied. Thus, we considered the instrument/operator team to be acceptable prior to screening in the field in terms of precision, but both instruments were felt to require recalibration before actual field use to correct for the low bias we observed on reference materials during the 10-day prescreening trial runs.

Precision for DT-60A, on a monthly basis during the actual screening program, is reported in Table 2. Coefficients of variation never exceeded 4.8 percent and were typically 3 percent or less. Data for DT-60B were similar and therefore are not repeated. It should be noted that CV values did not substantially improve with either instrument as the experience of the screeners increased.

The results of linear regression analysis comparing each DT-60 separately against the Abell-Kendall Manual Reference Method data are reported in Table 3. As indicated, each DT-60 correlated highly with the Abell-Kendall values ($r = 0.99$ for each), and both showed a slightly negative proportional bias (linear slope <1.0) but a positive y intercept. Table 4 reports the mean and average bias of each DT-60 compared with the Abell-Kendall Reference results for all patient samples run (total cholesterol by reference method ranges from 2.75 mmol/L to 9.55 mmol/L). Figure 1 is a Bias Plot comparing the DT-60 instruments with the matching Abell-Kendall Reference Results. The plot provides visual confirmation of the bias data reported in Table 4.

Discussion

The major criteria by which to assess reliability of cholesterol testing are precision and accuracy.

Precision is defined as the ability of an analytical system to obtain comparable values on repeated testing, typically

TABLE 1—Precision during 10 Days of Pre-Screening/Training Period

Instrument	Number of Observations	Target Cholesterol Value of Reference Material (mmol/L)	Minimum Cholesterol Value Observed (mmol/L)	Maximum Cholesterol Value Observed (mmol/L)	Mean of Cholesterol Observations (mmol/L)	Coefficient Vairation (CV) (%)
DT-60A	40	2.60	2.25	2.70	2.50	3.87

*range of values 2.75 mmol/L to 9.55 mmol/L
**Biases calculated using cholesterol values originally determined in mg/dl.

expressed by the *coefficient of variation* (CV), defined as one standard deviation divided by the mean of repeated determinations × 100. The *total* (or between-run) coefficient of variation is a measure of a method's variability over many days, whereas *within-run* precision is a measure of variance during a single run. Lippel, *et al*, noted that total precision is usually worse than within-run precision for cholesterol because there are many more sources of variability from run-to-run than would be likely within a single run.[8] The National Cholesterol Education Program has advised that the total CV should be 5 percent or less, and most laboratories now participating in the College of American Pathologists standardization program report total CV under 3.5 percent.[7]

Accuracy is defined as agreement of the test result with the "true value." The most frequently used cholesterol reference method is the manual Abell-Kendall method utilized by the Centers for Disease Control (CDC), generally assessed by comparing cholesterol values obtained by the test method to those of a laboratory whose accuracy has been "traced" back to an accepted reference method, such as that available at the CDC.[7] The Laboratory Standardization Panel of the NCEP has recommended that laboratories achieve an *average* bias less than or equal to ±3 percent within the next

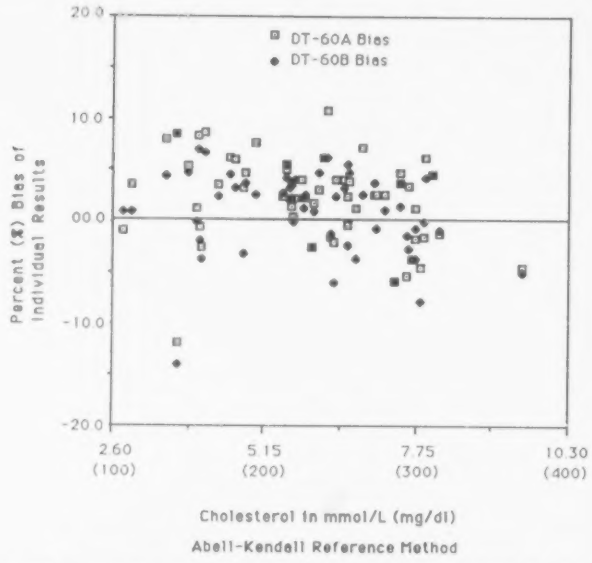

FIGURE 1—Bias Plot Comparing Individual DT-60A and DT-60B Results against the Cholesterol Concentration Determined by the Abell-Kendall Reference Method on Venous Serum Split Samples

five years.[7] Average *bias* is determined by subtracting the mean of a *group* of patient samples run on a new method from the mean of those samples determined using the reference method and then dividing the difference by the mean of the reference method.

Portable cholesterol testing instruments have been available since approximately 1979,[9] and a number of precision and accuracy assessments using portable testing devices have been reported.[4,5,6,10–13] However, previous studies have generally not been performed in screening settings where frequent movement of potentially sensitive equipment, large numbers of different screening personnel with varying degrees of laboratory experience, large patient volume, and changes in environmental temperature and humidity could influence the reliability of test results. The specific purpose of this study was to simulate a community mass screening program and to assess laboratory measurement reliability in a true field setting over an extended time period.

Under the conditions of this study, we noted acceptable results for both precision and accuracy during four months of screening for total cholesterol using either of two DT-60 analyzers we had purchased. Variability remained stable over the entire screening period suggesting that CVs of 3.0 percent may be the best one can achieve under conditions similar to those we encountered. These values for precision and accuracy fall within those recommended as goals for clinical laboratories to achieve by 1993.[7] Thus, assuming operational conditions no worse than those we encountered, one could expect this analysis system to provide both precise and accurate total cholesterol determinations in a public screening setting.

Caution should be exercised in extrapolating results of this study to all screening programs and settings. The results we obtained are probably representative of the range of precision and accuracy values that screening programs might achieve, but a number of variables in other programs could lead to differences. For example, each analyzer is slightly different, as our results showed. Even when instruments are

calibrated using identical materials and operated by the same personnel, results from one instrument to another will vary. We would recommend, therefore, that screening personnel perform assessments of instrument accuracy and precision before undertaking public screenings and ensure that these variances are within accepted laboratory standards. We do not recommend that screening teams rely exclusively on reported biases or precision levels since, as the literature now clearly shows, these may vary from instrument-to-instrument and from operator-to-operator.[6,12,14] These results also cannot necessarily be extrapolated to other types of portable blood analyzers such as the Reflotron by Boehringer-Mannheim or the Vision system by Abbott. To date, reports based on the Reflotron have suggested that neither accuracy nor precision are as acceptable in screening as the results reported here.[15,16] No data have been reported concerning the Abbott system in a screening situation.

In conclusion, we found that a trained group of screening personnel using a portable blood analyzer system yielded acceptable precision and accuracy in a demanding screening-type field setting. We expect that similar results could be achieved by other groups when utilizing equally rigorous surveillance of results and comparable instrumentation.

Report Shows 16 Alzheimer's Medicines in Development

A new report has been released by the Alzheimer's Association and the Pharmaceutical Manufacturers Association (PMA) showing that 16 medicines are being developed by 11 pharmaceutical companies to treat Alzheimer's disease (AD) and its related symptoms.

The report, titled *Alzheimer's Medicines in Development*, lists chemical and trade names of each drug, as well as its developer and development status. All the medicines in the report are in human testing in the United States.

Alzheimer's disease costs Americans close to $80 billion a year and currently affects an estimated 4 million Americans.

Although none of the test medicines is expected to be a cure, they do represent important progress toward easing the symptoms of Alzheimer's disease.

A copy of the report may be obtained by writing the Alzheimer's Association, 70 E. Lake Street, Suite 600, Chicago, IL 60601; or the Pharmaceutical Manufacturers Association, 1100 15th Street, NW, Suite 900, Washington, DC 20005.

Demographic and Dietary Determinants of Constipation in the US Population

ROBERT S. SANDLER, MD, MPH, MATTHEW C. JORDAN, MS, AND BRENT J. SHELTON, BS

Abstract: We investigated the association between self-reported constipation and several demographic and dietary variables in 15,014 men and women 12–74 years of age examined between 1971–75 during the first Health and Nutrition Examination Survey. Overall, 12.8 percent reported constipation. Self-reported constipation correlated poorly with stool frequency. Nine percent of those with daily stools and 30.6 percent of those with four to six stools/week, reported constipation. Constipation was more frequent in Blacks (17.3 percent), women (18.2 percent), and those over age 60 (23.3 percent); after adjusting for age, sex, and race it was more prevalent in those with daily inactivity, little leisure exercise, low income, and poor education. Constipated subjects reported lower consumption of cheese, dry beans and peas, milk, meat and poultry, beverages (sweetened, carbonated and noncarbonated), and fruits and vegetables. They reported higher consumption of coffee or tea. They consumed fewer total calories even after controlling for body mass and exercise. (*Am J Public Health* 1990; 80:185–189.)

Introduction

Constipation is a significant problem in the United States with over 330 million dollars spent each year on over-the-counter laxatives.[1] Our understanding of both the epidemiology and pathophysiology is limited.

Studies of constipation are handicapped by lack of a standard definition of the condition. Connell, *et al*,[2] inquired about the bowel habits of 1,055 persons not seeking medical advice in an industrial community. They found that 99.4 percent had three or more bowel movements per week. Based on this work, individuals with fewer than three stools per week are usually considered to be constipated. While physicians and investigators often define constipation by stool frequencies that lie below the usual range, healthy subjects tend to define constipation in terms of function (straining) and stool consistency (hard stools).[3]

Because of the lack of a standard definition, because bowel habits change with time, and because constipation depends on age and sex, the range of reported prevalence is quite broad. In a group of healthy young adults not seeking health care, Sandler and Drossman found that 7.3 percent reported that they were constipated more than 25 percent of the time.[3] When constipation was defined as straining more than 25 percent of the time, Thompson and Heaton found that 10.3 percent of subjects were constipated.[4] In a prospective study of 1,064,004 men and women who were surveyed by American Cancer Society volunteers, 18.5 percent of men and 33.7 percent of women reported "constipation."[5]

Sonnenberg and Koch have recently performed detailed analyses of constipation using data from the National Hospital Discharge Survey, the National Health Interview Survey, the National Ambulatory Medical Care Survey, and the Vital Statistics of the United States.[6] Constipation was the most frequent digestive compliant in the United States with an estimated four million people complaining of "frequent constipation." There were over 92,000 annual hospitalizations with constipation listed among the hospital discharge diagnoses, and 900 deaths from diseases associated with or related to constipation. Using data from the National Disease and Therapeutic Index, the same authors reported 2.5 million physician visits for constipation.[7] The data are limited in several ways. Most people with constipation do not visit physicians, are not hospitalized, and do not die. The reliability of the prevalence estimates for chronic constipation based on the National Health Interview Survey are uncertain because one member of the household provided health information for all members of that household. The published reports of constipation have not attempted to link constipation with dietary and lifestyle factors that might be responsible for this symptom.

The first National Health and Nutrition Examination Survey (NHANES-I) was conducted by the National Center for Health Statistics between 1971–1975.[8] The study involved a nationwide probability sample of 20,749 persons. In addition to detailed socio-demographic information, the survey included data on dietary intake, exercise, and bowel dysfunction. We took advantage of unique data available from the NHANES-I to describe the distribution and determinants of constipation in the United States.

Methods

The NHANES-I was a large-scale, multistage probability sample designed to closely reflect the US non-institutionalized civilian population, 1–74 years of age. The design and methodology have been described in detail elsewhere.[6] The analyses reported here involve 15,014 Black and White persons older than age 12 at the time of the survey, who completed both an examination and a dietary interview.

Constipation, in the present study, was based on responses to the question: "Do you have trouble with your bowels that makes you constipated or gives you diarrhea?" Those who answered "yes—constipated," were defined as having self-reported constipation and were compared to those who responded negatively to the question. Those with diarrhea (621), constipation and diarrhea (73), and those with missing information (72) were excluded. Subjects were also asked: "How often do you usually have a bowel movement?" Stool frequency was coded by the National Center for Health Statistics as less than two stools per week, two to three per week, four to six per week, one per day, and two or more per day. It was not possible to analyze stool frequencies apart from these categories. An alternative definition of constipation was fewer than four stools per

© 1990 American Journal of Public Health 0090-0036/90$1.50

week. No time period for self-reported constipation or stool frequency was specified.

Height and body weight were obtained through standardized procedures.[6] Body mass index (BMI) was calculated using the formula BMI = weight (kg.)/height $(m)^2$ to provide an index of weight controlled for height. Daily calories were determined using standardized food composition tables applied to foods in each person's 24-hour dietary recall record. Subjects were also asked the frequency with which they consumed a variety of foods with categories chosen to provide reasonably balanced numbers in each category. Race was dichotomized as White or Black.

Analyses were performed using the Statistical Analysis System (SAS Institute, Cary, NC). The SESUDAAN program, which takes into account the complex sample design of the survey, was used to compute standardized proportions and standard errors.[9] The RTILOGIT program[10] was run under SAS to perform logistic regression analyses that took account of the sample weights and sample design. Age, body mass index, and calories were entered into models as continuous variables. Categorical variables were coded as described in the Tables.

Results

Overall, 12.8 percent (S.E. 0.48) of the United States population reported constipation (Table 1). Self-reported constipation was more common in Blacks (17.3 percent), women (18.2 percent), and those over age 60 (23.3 percent). When we defined constipation as fewer than four stools per week, constipation was again more common in Blacks and women. The elderly did not consistently report fewer stools.

There was poor correlation between the reported stool frequency and self-reported constipation (Table 2). Only 67.8 percent of those with fewer than two stools per week reported constipation. Nine percent of those with daily stools, and 30.6 percent of those with four to six stools per week considered themselves constipated. Of the 180 persons with less than two stools per week, 137 (76 percent) were women, supporting the fact that constipation is more common in women.

Self-reported constipation was most prevalent in those with daily inactivity and little recreational exercise with a distinct gradient from the most active to the least active at all ages (Table 3). Those with low income and education were more likely to be constipated within each age category. The effect of marital status was inconsistent. Reported constipation was slightly more common in those living in the South. When we stratified by race and sex (not shown), all of these findings persisted. They also persisted when we compared those with fewer than four stools per week (constipated group) to those with more than four.

Table 4 presents data on a number of specific dietary constituents. Constipated individuals reported lower consumption of cheese and cheese dishes, dry beans and peas, milk, fruits and vegetables, meat and poultry, and sweetened, carbonated and non-carbonated beverages, and higher consumption of coffee and tea. There was no consistent relationship with cereal or bread. These associations largely persisted for White men and women and when we defined constipation as fewer than four stools per week. The results for Blacks were not as consistent but were based on much smaller numbers within individual dietary categories.

In order to assess the independent effects of these variables, we examined them in a logistic regression model that also contained terms for age, race, sex, body mass index, and total daily calories. Each individual dietary item was

[a]Cheese refers to cheese and cheese dishes; beans to dry beans and peas; beverages to sweetened, carbonated and non-carbonated. The categories for the following specific items were: *milk*: (1) never, (2) less than once a week, (3) 1–6 times a week, (4) once a day, (5) more than once a day; *meat and poultry, fruits and vegetables, bread*: (1) never, (2) less than once a week, (3) 1–6 times a week, (4) 1–2 times a day, (5) more than twice a day; *cheese, beans*: (1) never, (2) less than once a week, (3) 1–2 times a week, (4) 3–6 times a week, (5) once or more a day; *cereal*: (1) never, (2) less than once a week, (3) 1–6 times a week, (4) one or more times a day. *Beverages* (sweetened, carbonated and non-carbonated) and *coffee or tea* were ranked in four categories by the NCHS (1) never, (2) less than once a week, (3) 1–6 times a week, (4) once or more a day.
[b]SEM = Standard error of the mean.

statistically significant ($p < 0.001$) in the same direction as the univariate analyses shown in Table 4.

Body mass index was similar for those who reported constipation and those who did not at every age and in both sexes, whereas the constipated group consumed fewer calories (Table 5). In order to assess the independent effects of various demographic and lifestyle factors on reported constipation we performed a logistic regression analysis that simultaneously controlled for all variables in the model and took into account the sample weights and sample design (Table 6). The most important determinant of constipation was sex. Women were 2.4 times more likely to report constipation after controlling for other factors. The other results were in the same direction as the univariate analyses. Constipation was more common in Blacks, the elderly, and those with less education, low income, and inactivity. Marital status and body mass index were not important. Constipated subjects consumed fewer calories even after controlling for the other variables in the model.

Discussion

Our results are representative of the non-instiutionalized civilian US population. The large size of the study (15,014 subjects) permitted us to look at several demographic and dietary characteristics in order to present a more complete description of constipation. The results confirm other reports and indicate that recreational and nonrecreational inactivity is associated with self-reported constipation independent of dietary intake. Exercise is thought to increase propulsive movements in the large intestine[11] although there are not good studies to support the use of exercise in constipated subjects.[12]

The NHANES-I survey was conducted between 1971 and 1975. There has been a modest decrease in the prevalence of "frequent constipation" between 1968 and 1986.[6] We chose the first NHANES-I because subjects were asked about both stool frequency and self-reported constipation. There were only 180 subjects with fewer than two stools per week, too few to permit detailed analyses. We performed all analyses using stool frequency less than four per week (8.6 percent of the population) as well as self-reported constipation, and found no major differences in the results for diet and demographic features with one exception. The elderly did not report consistently fewer stools than the young even though they reported more constipation.

In the absence of an agreed upon definition of constipation, we believe that self-reports of the symptom of constipation may be preferable to stool frequency since infrequent stools may be asymptomatic and simply represent the lower end of the continuum. Self-reported constipation may refer to several different symptoms including infrequent stools, feelings of incomplete evacuation, straining and hard stools[3] which may, in turn, be the consequence of several discrete pathogenetic mechanisms. It is possible that the differences that we observed in constipation prevalence by age, sex, and race are due to differences in definitions used by respondents. The similarity of our age and sex findings to those based on physician diagnosis, however, argues against this interpretation.[7]

There is value to studying self-reported constipation since it is this symptom that distresses patients. Epidemiol-

[a]Adjusting simultaneously for all other variables in model using RTILOGIT[10] to take account of sample weights and sample design. For education, income, nonrecreational activity, and recreational activity, betas (and odds ratios) reflect comparisons between individual categories described in Table 3. Age and body mass index were entered as continuous variables with betas calculated for intervals of 10. Total calories were entered as a continuous variable with the beta reflecting an interval of 1000 calories.

ogists have been reluctant to study conditions for which there may not be pathologic, radiologic, or laboratory confirmation. We need to study the epidemiology of symptoms and symptom complexes, however, since they represent a large part of human morbidity and suffering.[13]

Diet, particularly dietary fiber, has often been regarded as an important determinant of constipation,[14,15] although personality factors may be important as well.[16] The large sample size and detailed dietary data available in the NHANES-I permitted us to examine the association between diet and constipation. We found that those who ate more fruits and vegetables had fewer complaints of constipation. In addition, however, we found that those who ate more of a number of dietary constituents including cheese, dry beans and peas, milk, and meat and poultry also had less self-reported constipation. As one might expect, these individuals also had a higher caloric intake. When we controlled for caloric intake, however, these dietary components were still significant.

One of the most interesting findings was that constipated subjects ate fewer calories. The constipated group was not leaner, and their lower calorie consumption was not completely explained by decreased physical exercise or differences in other demographic characteristics, although these could have been incompletely controlled in the logistic model (residual confounding). The inverse association between calorie consumption and self-reported constipation may offer clues about etiology. Caloric intake is based on body size, physical activity, metabolic efficiency, and net energy balance (i.e., change in body fat or muscle).[17] The mechanisms of metabolic efficiency, including differences in absorption and thermogenesis, are poorly understood, but individual differences must exist since even under controlled conditions some subjects will gain more weight than others eating similar calories.[18]

One might hypothesize that individuals with constipation are more efficient at absorbing or utilizing food in their small intestines. They eat less, present less to their colons, and have more constipation as a consequence. Those free of constipation, on the other hand, are less efficient. Food that escapes absorption enters the large bowel where fecal flora may produce short chain or volatile fatty acids that protect against constipation.

The absorption of dietary constituents by the human small bowel is known to be incomplete. Kramer, *et al,*[19] found that several different dietary components increased the ileal effluent in seven colectomized subjects. The starch moiety of most staple foods (wheat, corn, oats, potatoes) is incompletely absorbed by normal subjects,[20] and there may be considerable variation among individuals. Stephen, *et al,*[21] found that while some individuals absorbed starch well, others failed to absorb 15–20 percent. It is possible that functional constipation could be due to overly efficient handling of the carbohydrate that normally escapes absorption in the small bowel.[22]

In summary, we found that self-reported constipation was more common in women, Blacks, the poor, the elderly, and those with less education and little physical exercise. Those who ate fewer calories were more constipated even after controlling for exercise and body mass index. In order to reconcile all of the available information, one might view constipation as the end result of both exogenous factors (diet and exercise) and endogenous factors (sex hormones, personality, and metabolic efficiency). Further studies on energy balance and absorption in constipated subjects may be important in helping us to understand and treat this common symptom. Such studies will require large numbers and careful consideration of symptom definition.

Nation's First Medical School Celebrates Its 225th Anniversary throughout 1990

The University of Pennsylvania School of Medicine—the first medical school established in the United States in 1765—marks its 225th anniversary during 1990, at the same time the University notes its 250th anniversary. A year-long celebration is planned to celebrate this landmark in the history of American medicine. A blend of history, contemporary scholarship, and a look at the future will be linked with festivities to make 1990 a memorable year for alumni, faculty, students, and friends.

The continuing theme throughout the year will be the evolution of medicine in the United States and the critical role the University of Pennsylvania School of Medicine played in the process, accentuated by exhibits, lectures, symposia, and exchanges to highlight the major contributions of the school. Three peak celebration periods are planned for the year—occurring in January, May and October.

- The January program emphasized frontiers of science in medicine, and centered around the dedication of a new clinical research building on the site of the former Philadelphia General Hospital. Louis Sullivan, MD, US Secretary of Health and Human Services, delivered the keynote address which focused on national health policy. Other events in the January program included the 27th annual Women in Medicine dinner, and a scientific symposium entitled "Molecular Mechanisms of Disease" featuring three of the world's foremost medical scientists: Philip Leder, MD, Harvard University; Sydney Brenner, MD, Cambridge, England; and Joshua Lederberg, PhD, Rockefeller University.
- The "May Festival" will take place May 16–20, and will include dedication of the Seymour Gray Foundation for Molecular Medicine: Seymour Gray Lecture in Molecular Biology. Keynote speaker will be Michael S. Brown, MD, Nobel Laureate and Professor of Molecular Genetics, University of Texas-Southwestern Medical School. "Medical Alumni Weekend" a major annual event—will be incorporated into the festivities, with numerous social activities, and a scientific symposium entitled "Recent Developments in Cancer Research."

Also in May, continuing medical education credit will be given for a series of faculty-alumni exchanges that are part of the Medical School's 225th anniversary.

- The "Future of Medicine and Health Care" will be the focus of the October festivities, with a symposium on October 12 featuring three keynote speakers: Arnold Relman, MD, Editor, *New England Journal of Medicine*; Samuel O. Thier, MD, President, Institute of Medicine/National Academy of Sciences; and Uwe E. Reinhardt, PhD, Professor of Political Economy, Princeton University.

Epidemiologic Assessment of Screening Tests for Antibody to Human T Lymphotropic Virus Type I (HTLV-I)

RIMA F. KHABBAZ, MD, TRUDIE M. HARTLEY, MT, MICHAEL D. LAIRMORE, DVM, PHD, AND JONATHAN E. KAPLAN, MD

Abstract: We tested 196 sera from a human T lymphotropic virus type I (HTLV-I) risk group (prostitute women) with two commercial "research" enzyme-linked immunoabsorbent assays (EIA) for HTLV-I antibodies. All tested sera were characterized by HTLV-I Western immunoblots and by HTLV-I radioimmunoprecipitation assays. The estimated sensitivities of the EIA tests were 93.8 percent and 100 percent, and the specificities were 98.8 percent and 95.8 percent, respectively, using recommended criteria for seropositivity (requiring reactivity to both *gag* p24 and *env* gp46 or gp61/68). Calculated negative predictive values remained excellent (>99.9 percent and 100 percent, respectively) at lower seroprevalence rates but the positive predictive values were only 7.3 percent and 2.3 percent when calculated for a seroprevalence rate of 0.1 percent. These results emphasize the importance and need for additional HTLV-I supplementary serologic testing when screening populations with low HTLV-I seroprevalence rates. (*Am J Public Health* 1990; 80:190–192.)

Introduction

Human T lymphotropic virus type I (HTLV-I), the first human retrovirus discovered,[1] is causally linked to adult T-cell leukemia/lymphoma (ATL)[2] and has been more recently associated with a progressive myelopathy known as tropical spastic paraparesis (TSP) in the Caribbean and as HTLV-I-associated myelopathy (HAM) in Japan.[3,4] HTLV-I infection is endemic in southwestern Japan, the Caribbean, and in part of Central America and Africa.[5] In the United States, elevated rates of infection have been reported in intravenous drug users[6,7] and in recipients of multiple blood transfusions,[8] raising concerns about the safety of the nation's blood supply. A recent study of random blood donors in eight US cities showed a seroprevalence of 0.025%.[9]

Screening tests for antibodies to HTLV-I were licensed by the Food and Drug Administration (FDA) in November 1988, and the FDA has recommended that these tests be used to screen blood donated for transfusion.[10] The purpose of our study was to evaluate two commercially available HTLV-I enzyme-linked immunoabsorbent assays (EIA)* using a set of sera from a population at high risk for HTLV-I infection, and to estimate the predictive values expected with these tests when testing populations or when screening blood donors from populations with low rates of infection.

Methods

Serum Specimens

The 200 serum specimens used in this study were systematically chosen (every 7th specimen until a total of 200 were obtained) from a set of 1,541 sera from US prostitutes with a high HTLV-I seroprevalence rate (7 percent).[11] All specimens had been frozen and stored at the Centers for Disease Control (CDC) at −20°C and were thawed for this study.

HTLV-I Antibody Testing

All serum specimens were tested by two HTLV-I EIAs (Dupont Co., Wilmington, DE, and Cellular Products Inc., Buffalo, NY); both used viral lysates from HuT-102-infected cells and differed mainly in their respective manufacturer's recommended cutoffs: 0.6 × mean of positive controls for Dupont's and 0.25 × mean of positive controls for the Cellular Products'. Initially reactive sera were retested in duplicate and classified as reactive or nonreactive for the test based on the manufacturer's recommendation. Because we needed to know whether each specimen was positive, indeterminate, or negative (see following), 196 of the 200 serum specimens, including all those reactive in either screening test, were further tested by Western immunoblot (WIB) and by radioimmunoprecipitation assay (RIPA); four specimens, negative on both EIAs, were too small for us to do WIB or RIPA and therefore were excluded from further analysis.

WIB used an HTLV-I-infected cell lysate purified from MT-2 cells (Hillcrest Biologicals, Cypress, Calif).[12] HTLV-I antigen was suspended in a sample buffer, heated at 95–100°C for four minutes, and subjected to electrophoresis in a single well of a 10 percent polyacrylamide gel (PAGE); PAGE-resolved proteins were electrophoretically transferred to nitrocellulose sheets and washed sheets were cut into 3.0 mm strips. Individual strips were incubated with 1:100 dilutions of serum overnight at 4°C, washed, incubated for 60 minutes at room temperature with 5 μg/ml biotinylated goat anti-human IgG (Vector Laboratory, Burlingame, CA). Strips were washed again and then incubated with avidin-biotin-peroxidase complex according to the manufacturer's instructions (Vector Laboratory, Burlingame, CA). Color reactions were developed with 3, 3'diaminobenzidine, nickel chloride and H_2O_2 (Sigma Chemical Co., St. Louis, MO).

For the RIPA, HTLV-I-infected MT-2 cells were metabolically labeled with [^{35}S]cysteine and [^{35}S]methionine (200 uCi of each nucleotide/ml/1 × 10^7 cells), disrupted in lysing buffer, centrifuged, and incubated with the sera. Immunocomplexes were precipitated with protein A-sepharose (Sigma Chemical Co., St. Louis, MO). Samples were analyzed by PAGE followed by autoradiography of dried gels.

In each test run, banding patterns were compared with those of a known positive serum, and a negative serum was included as a negative control. Specificity of banding patterns

This paper, submitted to the Journal February 10, 1989, was revised and accepted for publication July 11, 1989.

*At the time of this study these tests, which had not been licensed, were approved for research only.

was assessed by comparison with banding patterns on strips that had been incubated with monoclonal antibodies against HTLV-I-specific proteins (p19, p24 for WIB and gp61/68 for RIPA).[13,14]

Definitions

In this study, a seropositive serum sample was defined by the presence of antibodies to *gag* (p24) and *env* (gp46 or precursor gp61/68) on WIB or RIPA.[10] A serum sample with immunoreactivity to at least one HTLV-I gene product but not satisfying these criteria was called indeterminate. All remaining specimens were designated negative.

Calculation of Predictive Values

Negative and positive predictive values were calculated using sensitivity, specificity, and prevalence as outlined in Fleiss.[15]

Results

Of the 196 sera included in the analysis, 16 (8 percent) were HTLV-I seropositive by WIB or RIPA. Of those, seven fulfilled the seropositivity criteria on WIB alone; nine showed only *gag* reactivity on WIB and required RIPA to demonstrate antibody to *env*. Fourteen specimens (7 percent) were indeterminate after WIB and RIPA; all showed reactivity to *gag* gene products only, and no specimen showed reactivity on RIPA that did not also show reactivity on WIB. The remaining 166 specimens were negative.

Of the 16 seropositive specimens, 15 were repeatably reactive by Dupont EIA, for a test sensitivity of 93.8 percent, and all 16 were reactive by Cellular Products' EIA, for a test sensitivity of 100 percent (Table 1). Excluding the 14 serum specimens with indeterminate HTLV-I serologic results, the specificities of the tests were 98.8 percent and 95.8 percent, respectively.

Table 2 shows the positive and negative predictive values of these tests, calculated for different seroprevalence rates; the calculations were based on the sensitivities and specificities estimated in this study: the predictive value of a negative test result increased with lower seroprevalence levels and was >99.9 percent for Dupont's EIA at seroprevalence levels of ≤0.1 percent; the negative predictive value of Cellular Products' EIA was 100 percent for all seroprevalence rates. In contrast, the predictive value of a positive test result decreased with lower seroprevalence rates and was <8 percent for Dupont's and <3 percent for Cellular Products' at seroprevalence rates lower than 0.1 percent.

TABLE 1—HTLV-I Antibody Test Results of 196 Serum Specimens by Repeatable Reactivity in Two HTLV-I Enzyme-Linked Immunoassays

Results of Tests for HTLV-I	No. Repeatably Reactive	
	by Dupont's EIA*	by Cellular Products' EIA
Positive (N = 16)	15	16
Indeterminate (N = 14)	2	10
Negative (N = 166)	2	7

*At the time of the study these tests, which had not been licensed, were approved for research only; the recommended cutoff for the Dupont test has changed with licensure.

TABLE 2—Performance Characteristics of Two EIAs and Resulting Predictive Values for Different Seroprevalence Rates*

	Dupont's EIA		Cellular Products' EIA	
Sensitivity (b)	93.8%		100%	
Specificity (a)	98.8%		95.8%	
if:	PPV[§]	NPV[¶]	PPV	NPV
p = 8%	87.2%	99.5%	67.4%	100%
p = 1%	44.1	99.9%	19.4%	100%
p = 0.1%	7.3%	99.9%	2.3%	100%
p = 0.05%	3.4%	99.9%	1.2%	100%
p = 0.025	1.7%	99.9%	0.6%	100%

*Sera with indeterminate HTLV-I reactivities were excluded from these analyses.

[§]PPV = positive predictive value = $\frac{(b)(p)}{(b)(p) + (1-a)(1-p)}$, where b = sensitivity, a = specificity, p = prevalence

[¶]NPV = negative predictive value = $\frac{a(1-p)}{a(1-p) + (1-b)p}$

Discussion

This paper is not intended to be a comparison of the performance of the two tests. Neither test was licensed by the FDA at the time of the study and the recommended cutoff for the Dupont test has in fact changed with licensure* and is now similar to the Cellular Products' test. Rapid developments in the field may result in additional changes in these tests in the future. Rather, our data are intended to illustrate that both tests have low positive predictive values in groups with low prevalence of infection. Repeating the study with the currently licensed tests would not have changed this conclusion. Our data emphasize the need, with current assays, for more specific supplementary serologic testing before interpreting a sample as seropositive. Further serologic confirmatory testing must precede any decision to counsel a tested individual.

Our study suggests that, in populations with HTLV-I seroprevalence rates <0.1 percent, less than 10 percent of repeatably reactive test results might be found to be truly positive. While quite accurate for populations where sexually transmitted diseases and other infections are prevalent, these estimates of positive predictive value (PPV) must be more cautiously interpreted in screening US blood donors. In the American Red Cross study of 39,898 blood donors, for example, 10 of 68 specimens repeatedly reactive in a screening test were confirmed as positive for HTLV-I antibody, yielding a PPV of 15 percent.[9] This discrepancy is probably due to a higher specificity of the screening tests in the blood donor population. Specificity could not be calculated accurately in the American Red Cross study because supplementary testing was done only on EIA-reactive specimens, but specificities of 99.3 percent to 99.9 percent (compared with 98.8 percent and 95.8 percent in our study) have been estimated in blood donor populations.[10] Additionally, our

*Human T-lymphotropic virus type I (HTLV-I) Dupont HTLV-I ELISA: Product Insert Sheet

lower estimates of PPV could be the result of differences in the cutoff used to interpret these tests, and to technical differences in the supplementary serologic tests. Despite these discrepancies, it is still clear that PPVs are low in low-prevalence populations.

Our criteria for seropositivity have been recommended by the US Public Health Service Working Group[10] and require reactivity to both *gag* and *env* gene products; they currently necessitate at least Western blotting and in some instances WIB and RIPA as *env* reactivity appears to be better on RIPA than on WIB. The significance of indeterminate HTLV-I serologic results is not fully understood; these may represent nonspecific reactivity to cellular proteins, cross-reactivity with other unknown retroviruses, or early seroconversion to HTLV-I. The uncertainty regarding the significance of HTLV-I indeterminates resembles the situation with human immunodeficiency virus (HIV) where the full significance of sera with "indeterminate" HIV WIB remains to be determined[16]; further studies including serial serologic testing of persons with indeterminate HTLV-I serologies and examination of peripheral mononuclear cells with the new polymerase chain reaction (PCR) technique,[17] we hope, will provide evidence for or against viral infection. In analyzing our data, we excluded the indeterminates and thus avoided the issue of whether to count them as positives or negatives. Including the indeterminates with the positives would lower the calculated sensitivities of the screening tests; including them with the negatives would lower their specificities. Either way the resulting PPVs would be lower than the ones we calculated. For example, at a prevalence rate of 0.1 percent, including the indeterminates with the positives produces a PPV of 4.5 percent for Dupont's (compared with 7.3 percent) and 2.0 percent for Cellular Products' (compared with 2.3 percent); including them with the negatives changes the PPVs to 4.1 percent and 1.0 percent, respectively.

Based on our data, 11 to 21 percent of repeatably reactive specimens on EIA may be negative for HTLV-I antibodies (no bands on WIB). As blood is discarded from donors whose EIA results are repeatably reactive after screening, as much as 21 percent of discarded blood may be HTLV-I-negative. However, the objective of screening is an HTLV-I-free blood supply because HTLV-I is transmissible by transfusion of HTLV-I infected blood[18]; screening of the blood supply should achieve this. A limitation of current HTLV-I serologic tests, including WIBs and RIPAs, is that they cannot distinguish infection with HTLV-I from infection with HTLV-II, a closely related human retrovirus with no clear disease associations.[19] At present, HTLV-I and HTLV-II can be separated by amplification of viral specific sequences in infected cells using polymerase chain reaction (PCR).[20]

Comparison of Two Methodologies to Measure Agricultural Occupational Fatalities

DENNIS J. MURPHY, PHD, BARBARA L. SELTZER, BSN, MHA, AND CHARLES E. YESALIS, SCD

Abstract: Agricultural occupational fatalities in Pennsylvania for the years 1985–87 were followed up. Supplemental data concerning the occupation of the deceased and circumstances of the fatal accident were obtained from a family member. The number of fatalities designated as agriculturally and occupationally related by the National Traumatic Occupational Fatality (NTOF) system was compared with the number of fatalities identified by using alternative criteria for classification of agriculturally and occupationally related fatalities. There may be nearly a 30 percent error in the NTOF method resulting in a 20 percent undercount. (*Am J Public Health* 1989; 80:198–200.)

Introduction

The National Safety Council (NSC) estimates that agricultural industry fatalities for 1984* were 46 deaths per 100,000 workers[1] while the National Institute for Occupational Safety and Health (NIOSH) estimates them at 18.36 for the same year.[2]

The reliability and validity of the data used to generate these estimates have been questioned. Of specific concern is that these data are derived from information on death certificates regarding usual occupation, type of business or industry, and injury at work categories.[2–6] In agriculture, occupational work is difficult to distinguish from non-occupational work since the worksite is often the place of residence. This combination results in exposure to worksite hazards in both working and non-working situations and in both occupational and non-occupational activity.[7–9]

Additionally, the agricultural labor force is composed in part of individuals less than 16 years of age, individuals who work in other occupations on a full-time basis, and family members and relatives who may lend a helping hand only occasionally. These labor characteristics are not normally the case in other industries. Furthermore, agricultural land is often used for recreational purposes such as hunting, swimming, riding, etc, and for both non-occupational and occupational work. Lastly, differing methodologies are used to record and classify agricultural fatalities by the NSC and NIOSH.[1,2]

This paper compares the number of fatalities designated as both agricultural and occupational by the National Traumatic Occupational Fatality (NTOF) system, a system developed by NIOSH, with the number of fatalities identified by using alternative criteria for classification.

Methods

NIOSH developed the NTOF classification system to monitor occupational fatalities for all industrial sectors in the United States, including agriculture. The NTOF system collects and analyzes data on traumatic occupational fatalities using information from death certificates recorded by vital statistics reporting units in all 50 states and the District of Columbia.[2] These selected death certificates are then coded for the "usual industry" of the victim by divisional level industry categories listed in the Standard Industrial Classification Manual.[2,10] The assumption is made that "usual industry" at the divisional level is a proxy for the occupation engaged in at the time of the fatality. The number of death certificates coded into the agricultural industry are then considered agricultural occupational fatality cases.

We obtained copies of all death certificates for the years 1985–87 that indicated deaths that were accidental, and included "farm" or "agriculture" in any category (N = 141) from the Pennsylvania Department of Health, Division of Health Statistics and Research. For the same time period, a clipping service forwarded all newspaper accounts of farm and agricultural accidents and fatalities occurring in Pennsylvania.

The sample of fatality cases was reduced to 100 since only the death certificates that could be matched with a newspaper clipping containing the name and address of the deceased member's family were used. Of these 100 fatalities, 66 (66 percent) individuals from families of the deceased agreed to participate in the study. This group will hereafter be referred to as the supplemental data group.

A family member, usually a spouse, parent, or child of the deceased, was contacted by either telephone or mail to obtain supplemental data on the deceased's primary or usual occupation, secondary or part-time occupation, and the relationship between the activity at the time of the fatality and the deceased's primary or secondary occupation, non-occupational work, recreational pursuits, or other activities. The terms "primary or usual occupation" and "secondary or part-time occupation" were not further defined to the individuals questioned. Further information on the methodology

Ms. Seltzer is Research Assistant in that department at the University; Dr. Yesalis is Professor, Health Policy and Administration, and Exercise and Sport Science, at Penn State. This paper, submitted to the Journal March 13, 1989, was revised and accepted for publication June 26, 1989.

*The agricultural industry, as defined by Standard Industrial Classification (SIC) codes 01 through 09 includes production agriculture (farms, ranches, commercial orchards, truck gardens, etc.), various agricultural services, commercial hunting and fishing, and forestry, excluding logging.

© 1990 American Journal of Public Health 0090-0036/90$1.50

used to collect the supplemental data are detailed elsewhere.**

The alternative criteria for designating an agricultural occupational fatality included cases whose victims were:

- engaged in a work activity related to *either* their primary or secondary occupation of agriculture at the time of the fatality,
- under the age of 16 and engaged in a farm work activity, or
- under the age of 16 and injured by exposure to an agricultural worksite hazard although not engaged in an agricultural work activity.

Results

Our alternative criteria and the supplemental data were used as one data source when comparisons, explained below, were made. Because of the single data source, the effect of the alternative criteria and the supplemental information cannot be separated in this analysis. Table 1 compares characteristics of three groups: cases with supplemental data, cases that did not respond to our survey, and cases for which there was no match with a newspaper clipping. There are no differences between the 66 cases followed up and the other two groups.

Twenty-six of the 66 cases (39 percent) were identified by the NTOF criteria as agricultural occupational fatalities; the remaining 40 cases (61 percent) were excluded. Using the alternative criteria and supplemental information, 39 of the 66 cases (59 percent) were classified as agricultural occupational fatalities; the remaining 27 cases (41 percent) were excluded.

Of the 26 cases designated by NTOF as agricultural occupational fatalities, 3 (12 percent) were found to be non-agricultural occupational; the misclassification was due to relying on "usual industry" as a proxy for the occupation engaged in at the time of the fatality.

Sixteen of the 40 cases (40 percent) excluded by the NTOF criteria should have been classified as agricultural occupational fatalities. There were three reasons why these cases were missed by NTOF:

- In three cases, the "injury at work" category on the death certificate was either marked "no" or left blank.
- In seven cases, the fatality was from the secondary occupation of agriculture and secondary occupations are not listed on the death certificate.
- In six cases, the victim was under the age of 16 and was involved in farm work or was fatally injured from exposure to a worksite hazard.

Of the agricultural occupational cases NTOF did identify, three should *not* have been included. This means 19 of 66 cases were misclassified. However, because 16 cases were undercounted and three cases were overcounted, the net error was an undercount of 13 (20 percent) agricultural occupational fatalities.

The 27 cases that were excluded by our alternative criteria and supplemental data were examined to determine the specific reasons for their exclusion. These cases fell into four groups (Table 2) and are clearly non-agricultural and/or non-occupational.

Discussion

Our research suggests that there may be nearly a 30 percent error in the NTOF method for designating agricultural occupational fatalities which resulted in a 20 percent undercount of these fatalities. This error is due to problems of incomplete and inaccurate information on the death certificates, NTOF's limiting criteria for inclusion as an agricultural occupational fatality case, and the use of "usual industry" as a proxy for work engaged in at the time of the fatality.

Adjusting the NIOSH estimate (18.36 per 100,000 workers) upwards by 20 percent still leaves their estimate well short of the National Safety Council estimate (46 per 100,000 workers). There are at least two possible explanations for the remaining difference. One reason may be the different denominators each used. NIOSH used Census Bureau data for their denominator,[2] while the NSC used Bureau of Labor Statistics data.[1]

A second reason is that the NSC estimate may include some cases similar to the 27 cases that were excluded by our alternative criteria and supplemental data (we found 15 cases that involved non-occupational work). Death certificates do not differentiate

between occupational and non-occupational work, but unless supplemental data are collected, it is difficult to differentiate these fatalities. Differentiating fatal work accidents that are both agriculturally and occupationally related from those that are simply work related or that happen to occur on a farm or in a rural area is critical if agriculture, as an occupation, is to be fairly and accurately compared with other occupations.

The supplemental data collected in this study have additional benefits besides helping to more accurately identify agricultural occupational fatalities. This information can also yield information on non-occupational related injury and health problems. The Cooperative Extension, which has responsibility for farm and home safety education, can use this information to guide safety education and injury prevention activities. Yet another benefit is to assist state agencies to appropriately allocate resources for injury prevention.

The agricultural industry's unique workforce and workplace characteristics pose a greater challenge than most other industries for the tracking of its occupational work fatalities. The NTOF system is a good start for enumerating fatal agricultural occupational work cases at the national level and it is replicable for a single industry at the state level. This allows those interested in single industry state level data to conduct follow-up studies such as we have reported. These state studies can be used as a basis for state statistics, and for adjusting particular industry totals at the national level.

This study should be replicated in several states to better quantify errors of both the NTOF system for agriculture, and non-occupational fatal injuries in agriculture.

Use of OSHA Inspections Data for Fatal Occupational Injury Surveillance in New Jersey

MARTHA STANBURY, MSPH, AND MARCIA GOLDOFT, MD, MPH

Abstract: Occupational Safety and Health Administration (OSHA) computerized inspections data, death certificates, and medical examiner records identified 204 fatal occupational injuries in New Jersey, 1984–85. OSHA computerized data uniquely identified seven cases. They did not identify 35 fatalities under OSHA's jurisdiction, of which 24 were investigated by OSHA but not recorded, four were not considered work-related, and seven were not known to OSHA. Eighty-seven were outside OSHA's jurisdiction; 28 were among the self-employed who are not under the health and safety protection of any governmental agency. (*Am J Public Health* 1990; 80:200–202.)

Introduction

Surveillance data for fatal occupational injuries have been compiled in several states.[1–5] These data systems are based largely on death certificates, but are usually supplemented by one or more sources of data such as workers' compensation reports and medical examiner reports. Each source independently captures some fraction of cases. Another potential source of data for surveillance systems is data from occupational fatality investigations carried out by the Occupational Safety and Health Administration (OSHA). Investigation data are maintained in a computer database, OSHA's Integrated Management Information System (IMIS).

We examined the usefulness and completeness of these OSHA inspection data for New Jersey's fatal occupational injury surveillance system. The objectives were to determine: whether OSHA investigation data identified cases not captured on death certificates or medical examiners' records; and whether OSHA investigation data were available for all work-related deaths within OSHA jurisdiction that were identified from other data sources in the surveillance system.

Methods

Unintentional occupational fatalities were ascertained for calendar years 1984–85. A fatal occupational injury was defined as a death resulting from an unintentional workplace injury. New Jersey cases were identified from the New Jersey computerized death certificate file by a code that indicated unintentional injury at work and from medical examiner records by manually sorting through reports in the state medical examiner's office. Cases from each source were then merged into one computerized file by matching on the name of deceased.

© 1990 American Journal of Public Health 0090-0036/90$1.50

The New Jersey data were compared to OSHA fatality investigation data identified initially from the OSHA IMIS file. The OSHA IMIS file is intended to contain reports of all workplace investigations conducted by OSHA area office inspectors. Name of deceased, name of employer, and other investigative information are included in each record. Names of deceased in the IMIS file were matched with names from the merged death certificate/medical examiner file.

Next, a list of decedents was compiled from cases in the death certificate/medical examiner file for whom a record was not matched in the IMIS file, but whose workplaces appeared to be under OSHA jurisdiction. Jurisdiction was determined by reviewing information about each decedent's workplace available on the death certificate and medical examiner report. Employers in the public sector are not under OSHA jurisdiction. Almost all employers in the private sector are covered by OSHA, except where other federal agencies including the US Department of Transportation and the Federal Aviation Administration have jurisdiction.

The list of decedents' workplaces potentially under OSHA jurisdiction was sent to the OSHA regional office to determine whether these employers were, in fact, under OSHA jurisdiction. If so, the regional office was asked to determine whether an investigation was carried out that was not recorded in the IMIS computer file.

Results

OSHA IMIS data listed 77 fatalities for 1984–85. Sixty-three (82 percent) of these matched with cases in the medical examiner/death certificate file. Four of the remaining 14 cases were cardiovascular deaths and therefore did not meet the case definition. No death certificate could be found for three of the 14. This could have been due to name mispelling or to coding errors in the IMIS file. The remaining seven of the 14 met the case definition and were not captured in the New Jersey data sources (Table 1). Death certificates were obtained for these seven cases; coding errors explained why they had not been captured.

Two-hundred and four fatalities were counted by combining the IMIS data with the death certificate/medical examiner file. Table 2 shows OSHA jurisdiction of the 204 cases. Eighty-seven (43 percent) of the fatalities were outside of OSHA jurisdiction. Of the 105 under OSHA jurisdiction, OSHA IMIS identified 70 (67 percent) cases. Twenty-four investigations were carried out by OSHA area offices but were not recorded in the IMIS system. Of the remaining 11 fatalities under OSHA jurisdiction, OSHA claimed that in four cases the deaths were not work-related because the decedents had preexisting medical conditions (e.g., seizure disorder) related to the fatal episode, and therefore an OSHA investigation was not required. Seven cases of the 105 under OSHA jurisdiction were not investigated because OSHA was unaware of the fatality.

TABLE 1—Occupational Fatalities Identified in OSHA IMIS Data: 1984–85

	Number	%
Matches with death certificate/medical examiner file	63	81
False positives (cardiovascular deaths)	4	5
No death certificate found	3	4
True positives not matching death certificates/medical examiner file	7	9
Total cases in IMIS data file	77	100

TABLE 2—OSHA Jurisdiction for 204 Occupational Fatalities Identified in New Jersey 1984–85

Cases	Number (%)
Not under OSHA Jurisdiction	
Transportation	51
Government	8
Self-employed	28
Total not under OSHA jurisdiction	87 (43)
Under OSHA Jurisdiction	
Investigated according to IMIS data	70
Investigated according to OSHA regional office, not in IMIS	24
Not work related, according to OSHA Regional office	4
Not investigated; OSHA regional office unaware of fatality	7
Total under OSHA jurisdiction	105 (51)
Insufficient Data to Determine OSHA Jurisdiction	12 (6)
Total fatalities	204 (100)

Discussion

This study showed that the OSHA IMIS data file identified occupational deaths identified through no other source, but that it did not serve as a sole source of information because it did not capture all work-related deaths. Because IMIS data capture cases independent of other data sources, these data should be included in state-based fatal occupational injury surveillance systems. In addition, these data could be used as another source to estimate the true magnitude of fatal occupational injuries nationwide, following the procedures of Suruda.[6] However, there are several problems in utilizing these data, including the failure of IMIS data to accurately reflect the numbers of fatality investigations completed by OSHA area offices and underascertainment due to limited OSHA jurisdiction. The national OSHA Office of Data Analysis is addressing the first problem.

In a previous report, with incomplete case follow-up by the OSHA regional office, it appeared that as many as 34 percent of cases with employers apparently under OSHA jurisdiction were not investigated.* Other states using data on employers' fatality reports to OSHA had similar findings.[2,5] After exhaustive examination of case files by the OSHA regional office, it has been determined that a smaller proportion (7 percent) of cases under OSHA jurisdiction were not actually investigated by OSHA. Currently, death certificate and medical examiner data in New Jersey are being shared with the OSHA regional office to ensure that all occupational fatalities within OSHA's jurisdiction are investigated.

These data showed that nearly half of these New Jersey occupational deaths were outside of OSHA jurisdiction, of which 28 were among the self-employed, who are not under the health and safety protection of any governmental agency. Investigative data from OSHA have certain details about the circumstances of fatalities that are not in data from other

*Stanbury MJ, Goldoft M, O'Leary K: Data Sources for a Fatal Occupational Injury Surveillance System in New Jersey. Paper presented at the Annual Conference of the Society for Occupational and Environmental Health, April 6–8, 1987.

sources. Such details, which are important for injury prevention programs, are not available on these cases. Legislative changes are needed to address the large number of occupational deaths not under OSHA's jurisdiction.

ACKNOWLEDGMENTS

Dr. Goldoft compiled the death certificate and medical examiners' data while serving as an Epidemic Intelligence Service officer with the Centers for Disease Control. Opinions expressed in this paper are those of the authors and do not necessarily reflect the views of the Centers for Disease Control. We wish to thank Kathleen O'Leary, Allison Tepper, and Kenneth Rosenman for their helpful review of previous drafts of this paper, and also the staff in OSHA for their cooperation in following up on fatality inspection records.

Workplace Health Hazards: Analysis of Hotline Calls Over a Six-Year Period

JULIA QUINT, PHD, MARGARET HANDLEY, BA, AND KATE CUMMINGS, MPH

Abstract: Between 1981–1986 a state-based occupational health telephone hotline received more than 8,000 inquiries on over 3,000 hazardous agents. Major caller groups were employees (37%), employers (20%), health care providers, primarily physicians (19%), government agencies (12%), and labor unions (6%). Employees were the fastest growing caller group. Callers inquired about general health hazards of chemicals (65%), the relation of symptoms to work (22%), and risks to pregnancy (13%). (*Am J Public Health* 1990; 80:202–204.)

Introduction

In 1979, the California legislature enacted a right-to-know law with several support resources including the Hazard Evaluation System and Information Service in the Department of Health Services. As described elsewhere,[1] staff (toxicologists, physicians, industrial hygienists) perform a variety of functions, including operation of a publicly accessible telephone inquiry response system. Over 12,000 inquiries involving a cross-section of California workplaces have been received from 1980 through early 1989.

We present and discuss descriptive statistics which characterize inquiries received from 1981 through 1986.

Methods

Inquiry Intake Procedure

Information in the following categories is obtained from callers and recorded on a standard form after assuring confidentiality. Callers' concerns are grouped into one of three areas: effect on pregnancy; relation of symptoms to work; general health hazard information. Only one concern is recorded as primary; the order of priority (highest to lowest) is pregnancy, symptoms, general information. Callers are categorized as follows:

- *Employees:* persons calling on their own behalf regarding exposures in their workplace, self-employed individuals, and friends and relatives who call on behalf of employees.
- *Employers:* supervisors and managers, company health and safety and medical personnel and industrial hygenists.
- *Health care providers:* physicians, nurses, genetics counselors, poison control center staff and paramedics.
- *Governmental representatives:* California Occupational Safety and Health Administration (OSHA) personnel, city, county, state and federal personnel.
- *Others:* attorneys, news media representatives, volunteer organizations, educational institutions, etc.

Callers' characteristics and primary concerns were tallied from 1981 through 1986. Primary concerns by caller group were tallied from 1986 logs. Data on employee industries, occupations and agents and repeat callers were tallied from the 4th quarter, 1986. Industry data were available for 466 of 562 total inquiries.

Results

During the first four years of full service, there was a modest increase in the annual volume but in 1985 and 1986, the number of inquiries increased by 49 percent and 43 percent, respectively (Figure 1). The average number of inquiries during 1985 and 1986 (2,067) was approximately double the average (1,038) during 1981–84. The sudden increase in inquiry volume appears to be due to increased awareness regarding the potential health effects of chemical exposures at work.

In 1986, of the 365 employer inquiries received, 40 percent were from managers and supervisors, 29 percent were from health and safety personnel (other than industrial hygienists), and 24 percent were from industrial hygienists.

Of the health care providers who called in 1986, 67 percent were physicians (70 percent from private practices). Nurses (12 percent) and genetics counselors (9 percent) were the other major groups who called in 1986.

Approximately one-third of the government agency inquiries in 1986 were from California OSHA. The majority of these callers were industrial hygienists requesting information for worksite inspections.

Analysis of a subset of 1986 callers (562 inquiries received in the fourth quarter of 1986) showed that 39 percent of the employers, 36 percent of the health care providers, 33 percent

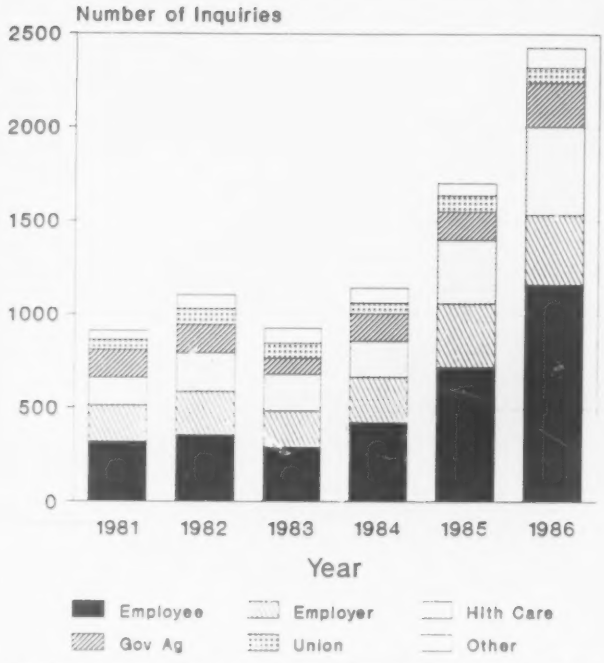

FIGURE 1—Number of Telephone Inquiry Response System Inquiries by Caller Group, 1981–86 (Caller groups defined under Methods)

of the union representatives, and 26 percent of the callers from government agencies were repeat callers. By comparison, only 2 percent of the employees had used the hotline previously.

Based on 466 inquiries from all callers in the fourth quarter of 1986, 48 percent concerned employment in service industries, 28 percent in manufacturing industries, and 8 percent in construction industries. The remaining inquiries concerned employment in transportation, communication, electric, gas, sanitary services (6 percent), agriculture (4 percent), public administration (4 percent), and retail (2 percent) industries. As a point of reference, the service industry was about 24 percent and the manufacturing industry about 18 percent of all non-agricultural California employees in 1986.[2] The types of industries included under services and manufacturing, along with typical occupations and agents of concern, are described in Tables 1 and 2, respectively.

Each year, multiple (10 or more) inquiries are received on 40 to 50 agents. The top 40 agents for which consultations were provided in 1986 are listed in Table 3.

Most caller concerns fall into three major categories. Average percentages of total inquiries for each category from 1981 through 1986 were 65 percent for general health hazard information, 22 percent symptom-related, and 13 percent pregnancy outcome.

The number of pregnancy-related inquiries received between 1981 and 1986 varied greatly. From 1981 through 1983 an average of 56 inquiries were received per year compared to an average of 375 inquiries per year from 1984 through 1986. A complete analysis of the pregnancy inquiries will be published in a separate report.[3]

Further analysis of 584 symptom-related inquiries received in 1986 showed that most were from employees (51 percent) and health care providers (26 percent), mainly physicians. Small percentages of symptom inquiries were from employers (8 percent) and government agencies (7 percent). California OSHA industrial hygienists inquiring about symptomatic employees encountered during worksite inspections represented about 60 percent of the symptom-related inquiries from government agencies.

Discussion

The preceding statistics clearly demonstrate that there is an increasing demand for acute and chronic health effects

TABLE 1—Service Industries,[a] Typical Occupations and Agents Inquired about during 4th Quarter, 1986

Industry	Occupation	Agents
Business (N = 86)[b,c]	Office workers	Video display terminals (VDTs), carbonless copy paper, photo copier chemicals, paint, carpet glues, indoor air contaminants, pesticides, asbestos
	Indoor pesticide applicators	organophosphate pesticides
	Photographers, photo lab technicians	amines, formaldehyde, hydroquinone
	Custodians	alkalis, alcohols, cleaners containing glycol ethers
Personal (N = 34)	Cosmetologists	hair dyes
	Manicurists	acrylic nail products (acrylates)
	Dry cleaners	perchloroethylene
	Laundry workers	alkalis (various products)
Health (N = 32)	Dental lab technicians	mercury, epoxy resins
	Histology, pathology lab technicians	formaldehyde, xylene, alcohols
	Hospital lab technicians	biological hazards, radiation
	Dental assistants	nitrous oxide, methyl methacrylate, mercury, formaldehyde
	Nurses	antineoplastic drugs, ethylene oxide, organic solvents
	Anesthesiologists	nitrous oxide, anesthetic waste gases
Educational (N = 18)	Teachers	PCBs, carpet glues, indoor air contaminants, photocopier chemicals, asbestos, fluorescent lights
	Librarians	asbestos
Miscellaneous (N = 18)	Artists	lead, dyes, pigments
Miscellaneous Repair (N = 16)	Welders	welding fumes, metals
	Furniture refinishers	methanol, methyl ethyl ketone
Auto Repair (N = 9)	Mechanics	asbestos
	Car painters and strippers	methylene chloride, toluene, xylene, phenols, isocyanates (specialty paints)

information for workplace exposures. Provision of this information is the core of the Hazard Communication Standard.

Eighty percent of all employers calling in 1986 wanted general health hazard information (such as acute and chronic health effects and industrial hygiene information), suggesting that this group needs further assistance to meet fully the challenge of its responsibility.

Of the various callers, employees are the largest and fastest growing subset. In 1986, 38 percent of all employees were primarily concerned with general health hazard information while 36 percent called about pregnancy concerns and 26 percent called because they had symptoms. Calls from health care providers closely paralleled this distribution. Both employee and health care provider symptom calls focused largely on acute effects and required, for the most part, information and industrial hygiene interventions to reduce exposures.

The telephone hotline is sometimes a limited forum for disseminating useful information. Specifically, some callers need to be educated about basic principles of toxicology before their complex questions (e.g., what is the cancer risk?) can be answered.

The purpose of hotlines is to provide ready access to information rather than education. Perhaps the service would have broader impact if it targeted those individuals who can use and disseminate the technical information provided. Callers who would be potential targets for a technical assistance hotline (health care providers, government agencies, union representatives, and employers) are by virtue of their jobs in contact with many employees. Thus, the information provided to them may benefit many employees. The high percentage of repeat callers among these potential target groups indicates that the hotline, to some extent, has already established an identity as a technical assistance service.

Since hotlines do not necessarily present the best forum for some types of callers, we also publish and disseminate chemical fact sheets and other educational material.

Incentives and Competition in a Worksite Smoking Cessation Intervention

LEONARD A. JASON, PHD, SHYAMALANITA JAYARAJ, CARYN C. BLITZ, MARK H. MICHAELS, AND LORI E. KLETT

Abstract: We evaluated a worksite smoking cessation program that employed multicomponents including support groups, incentives, and competition. The combination of incentives and other components increased participation rates to over 80%. Forty-two percent of smokers were abstinent at six months, compared to 13 percent of a control group (difference 29 percent, 95% CI 9, 49). (*Am J Public Health* 1990; 80:205–206.)

Introduction

Klesges, Cigrang, and Glasgow[1] and Klesges and Cigrang[2] reviewed seven controlled worksite programs having incentives and/or competition. The average post-test cessation rate was 44.8 percent, and the follow-up cessation rate was 45.9% (if one study by Stachnik and Stoffeimayr[3] with an exceptionally high rate is excluded, the average 13-month follow-up rate was 26.1 percent).

In January of 1988, we began pilot work with a worksite incentive system, that built on our previous work.[4,a] We report the results below.

Methods

The intervention was composed of two parts: a three week quitting program, and six months of follow-up meetings. The two group leaders of the two groups were employees of the Experimental (intervention) company, who were provided training and consultation. One of the two groups met on company time in the late afternoon, the second group met during lunch. For the first three weeks, there were two meetings each week. For the next two weeks, there were weekly meetings. For the next four weeks, there were meetings every other week. For the last four months, there were group meetings on a monthly basis. Each meeting lasted from 40 to 50 minutes.

Incentives

Participants also could earn $10 for attending each meeting regardless of their smoking status. Following the end of the initial three-week program, participants could also earn $1 each day that they were abstinent up to $180 (six months), and for every 30 continuous days of abstinence an extra $30. At the end of the program, each participant who had been abstinent for at least the last two months was eligible to participate in a lottery, with the company contributing $50 for each person who quit in the program. (The company changed this policy at the end of the program by actually putting in $50 for each person who signed up for the smoking cessation program.)

Participants had the opportunity to compete in a team effort for additional incentives. Teams consisted of three members who worked together to quit smoking. The team with the largest number of days abstinent won a cash prize of $300 at the end of the program.

Participants also had the option of selecting a coworker "buddy" to aid in those times of temptation to start smoking again. At the program's end, each buddy was given an opportunity to select an item from a list of gifts.

Participants were not required to join a group. They could still participate and be eligible for other incentives. On a pre-intervention survey, 81 percent of Es indicated they wanted the group program, 4 percent only wanted the self-help book, 2 percent wanted to quit on their own, and 11 percent indicated that they might quit smoking. As for incentives, 91 percent requested payment at meetings, 94 percent payment of $1 a day for quitting, 98 percent for $30 for a month of continuous abstinence, and 93 percent for the lottery. Forty-five percent of Es selected a team and 57 percent selected a buddy. Participants earned an average of $237. Fifty-three percent of Es indicated they would not have tried to quit if the program had not been offered.

Control group smokers were not provided any program or incentives; the high rates of control participation can partially be explained by their interest in obtaining prepoint expired air carbon monoxide (CO) tests. In the CO test, participants first exhale completely, then take a deep breath, hold it for 20 seconds, expire half the air, then breathe into an impermeable plastic bag to provide a sample of carbon monoxide in their breath to be measured.[5]

Results

Pretest Comparability

Two companies agreed to participate in our worksite smoking cessation study. There were approximately 300 employees at the Experimental company and 260 at the Control company. Forty-two of the 52 Control company smokers and 53 of the 63 smokers in the experimental company agreed to be involved in this study.

The two populations were rather similar (Table 1). Experimentals had smoked longer than controls and had higher status jobs.

Program Impact

The experimental manipulation of support, incentives, and competition had a substantial effect on abstinence rates at the immediate post-test, six-month end-of-group meetings, and at the six-month follow-up (Table 2). Experimentals also had higher continuous abstinence rates and overall worksite quit rates (i.e., the percentage of all smokers, both participants and non-participants).

Most of the experimentals selected incentives and the support group, but several preferred to accept other incentives unrelated to group attendance. For two who only selected the self-help book plus incentives, one quit at the post-test and six-month end-of-group meeting, and both had quit by the 12-month follow-up. One who decided to quit on his own and also accept incentives was successful at the three

time points. Of the six experimentals who indicated maybe they would quit but would also accept incentives, only one quit at the immediate post-test, relapsed at the end of six-month group meetings, and had quit again at the six month follow-up.

Biochemical Verification

CO confirmations (ppm ≤ 9) were conducted at both experimental and control settings at the post point and end of the six-month meeting period. There was an 85 percent accuracy rate with self-reports. When discrepancies occurred, there are a number of explanations that could have explained the findings (e.g., exposure to second hand smoke, poor ventilation at home or in the car).

Discussion

The present study indicates that incentives and competition can be used effectively to increase participation in worksite smoking cessation programs. Overall worksite reductions were high because a large percentage of smokers participated in the program. It should be noted that worksite policies that allowed smoking at designated areas were introduced in both settings prior to the start of the intervention. Some of the effectiveness of the present program might be due to the smoking restriction policies at the experimental company.

One of the advantages of the present study was that experimentals could select those parts of the program that most appealed to them. Although most chose the groups and incentives, several of those who quit selected other materials and/or incentives. This suggests that different individuals might prefer different types of programs.

There are some limitations to the present study. There were several prepoint differences between the experimental and control companies, and these differences might have played a role in the outcomes. In addition, only two companies were used, and thus this research can only be considered a case study until it is replicated with larger samples.

Retirement and Primary Cardiac Arrest in Males

David S. Siscovick, MD, MPH, David S. Strogatz, PhD, Noel S. Weiss, MD, DrPH, and Gad Rennert, MD

Abstract: We investigated the association between retirement and primary cardiac arrest (PCA) in 126 male cases and controls, 25–75 years of age, without prior heart disease or comorbidity. After adjustment for age alone, retirement was not associated with an increased risk of PCA, (OR = 1.1; 95% confidence intervals = 0.5, 2.4). This lack of association was not uniform across age strata, however. In 10 of 19 discordant pairs 60 or more years of age, the control subject had been retired; in all seven discordant pairs under 60, the case had been retired (lower 95% CI of the relative risk = 1.9). (*Am J Public Health* 1989; 79:207–208.)

Introduction

Clinicians have long suspected that retirement might increase the risk of coronary heart disease (CHD).[1] Retirement represents one of several profound exit/loss events, such as widowhood, death of friends or relatives, divorce, and relocation, that become more prevalent with increasing age.[2] The literature on retirement and physical health is fairly small and marked by contradictory findings and important methodologic limitations.[3–5] We analyzed data from a community-based study of potential risk factors for primary cardiac arrest[6] to determine the influence of retirement. Since our study was restricted to persons who were clinically healthy, we were able to minimize potential bias related to the fact that poor health is one determinant of retirement.[7]

Methods

The design of this study has been presented in detail elsewhere.[6] Briefly, from reports by trained paramedics in Seattle and suburban King County, Washington between December 1979 and January 1981, all 1,250 cases of out-of-hospital primary cardiac arrest were identified. Cases were characterized by a sudden pulseless condition without evidence of a non-cardiac condition as the cause of cardiac arrest.

Because we required detailed information regarding the prior experience of each subject, we restricted the study population to married residents of King County, 25–75 years of age (779 cases). In addition, based on the emergency medical service report or a brief telephone screening interview with the spouses of potential cases, persons with the following conditions were excluded: a history of prior clinically recognized heart disease (492 cases), such as angina pectoris, myocardial infarction, coronary artery bypass surgery and graft, congestive heart failure, arrhythmias, cardiomyopathy, congenital or valvular heart disease; or comorbidity that "limited their usual activity" (103 cases), such as cancer, chronic lung, renal or liver disease. Thus, there were 184 cases eligible for inclusion in this study; they represented persons who appeared and acted as if they were "healthy" until the time of their primary cardiac arrest.

After each case was identified, a control subject matched for age (within seven years), sex, marital status, and urban or suburban residence was selected from the community using random digit dialing.[8] Spouses of potential controls were queried by telephone in a fashion similar to those of cases; potential controls with a history of prior clinically recognized heart disease or comorbidity were excluded. Of eligible subjects identified, the spouses of 89 percent of the cases and 85 percent of the controls complied with a more extensive in-home interview. Thus, there were 163 cases and 163 controls in our study population; 18 percent of subjects were female, 94 percent were White, and the mean age was 58 years.

The home interview verified the absence of prior clinically recognized heart disease or comorbidity and covered factors such as history of hypertension treatment, current cigarette smoking, habitual vigorous leisure-time activity, history of diabetes mellitus, and alcohol consumption. We also asked whether the subject was currently employed and, if not, whether the subject was retired and formerly employed, not working currently but temporarily laid off and seeking employment, or never employed. Information regarding the specific age of retirement and reasons for retirement was not obtained. These investigations were completed in 1981.

We restricted this analysis to the 127 male case-control pairs in which both members were either employed or retired. Among the six male case-control pairs that were excluded, four of the cases and two of the controls were temporarily laid off and seeking employment. One additional pair was excluded because of missing data related to employment status.

An unadjusted matched-pairs analysis and a conditional multiple logistic regression analysis for matched case-control data were used in this study.[9] Factors evaluated simultaneously using the matched-pair multiple logistic model included history of hypertension treatment, current cigarette smoking, habitual vigorous activity, and alcohol consumption. We included age as a continuous variable to control for residual confounding related to age. To explore possible differences between early and conventional retirement (as represented by age at interview), we used a dichotomous variable for age (<60 years, >60 years).

Results

Cases were more likely to be retired compared to controls (Table 1); comparing retired men with currently employed, the estimated relative risk was 1.7 (95% confidence intervals = 0.8, 3.4). However, the estimate of the relative risk was 1.1 either after adjustment for age alone (95% CI = 0.5, 2.4) or after simultaneous adjustment for age, history of hypertension treatment, current cigarette smoking, habitual physical activity, and alcohol consumption (95% CI = 0.5, 2.8).

TABLE 1—Distribution of Primary Cardiac Arrest Case-Control Pairs According to Retirement Status, King County, Washington, December 1979–January 1981

Retirement by Control	Retirement by Case	
	Yes	No
Yes	27	12
No	20	68

Among case-control pairs less than 60 years of age, cases were more likely to be retired compared to controls (Table 2); in all seven discordant pairs it was the case who had been retired (relative risk = infinity, lower 95% CI = 1.9). Of note, among subjects less than age 60, the prevalence of cigarette smoking, obesity, diabetes, family history of heart disease, and alcohol consumption was similar among retired and employed men; however, prior hypertension treatment was more common among retired (62 percent) than employed (25 percent) men. There was no relation between retirement and the risk of primary cardiac arrest among men greater than or equal to 60 years of age, as reflected by an estimated relative risk of 0.9 (95% CI = 0.3, 2.7).

Discussion

There are several limitations of our analysis: we did not obtain specific information on the reasons for retirement; we do not know the extent to which retirement was involuntary. However, our study was restricted to persons without clinically recognized heart disease or comorbidity that limited their usual activity; only 8 percent of subjects had more than three restricted bed days over the prior six months and less than 1 percent had more than six days. For these reasons, we consider it unlikely that physical disability was a major determinant of retirement in our study. Since we did not obtain information on the time since retirement began, we were not able to determine if this factor influenced the risk related to retirement. Finally, because of the small number of retired men in our analysis, we were not able to fully explore potential confounding related to other risk factors for the age-specific estimates of risk related to retirement.

We chose a cut-point of age 60 for early retirement because we considered retirement prior to that age unambiguously early. For a later cut-point, such as age 62, the magnitude of the increase in risk related to early retirement decreased (relative risk = 2.8, 95% confidence intervals = 0.9, 8.2) but the direction of the interaction between age and retirement on the risk of primary cardiac arrest remained the same. Nevertheless, for the reasons noted above, our finding of an increase in the risk of primary cardiac arrest among younger but not older men should be viewed as preliminary. Because of the magnitude of the association of retirement with primary cardiac arrest that we observed in relatively young men, the benefits and risks of early retirement deserve further study.

Seroconversion to Human Immunodeficiency Virus in Prison Inmates

C. Robert Horsburgh, Jr, MD, Joseph Q. Jarvis, MD, MSPH, Trudy McArthur, LPN, Terri Ignacio, RN, and Patricia Stock, RN

Abstract: We evaluated the prevalence and incidence of human immunodeficiency virus (HIV) infection in 3,837 inmates of a state prison system. Ninety-two (2.4 percent) were HIV-seropositive. The highest proportion of HIV-seropositive inmates was found among Blacks (5.4 percent), females, and those 30 years of age or older. HIV-seropositivity of entering inmates was also 2.4 percent and was unchanged over the three years of the study. Seroconversion occurred in two inmates while in prison, a rate of one conversion per 604 person-years, but HIV infection could have occurred before entry. Seroconversion to HIV was rare in inmates in this correctional facility (*Am J Public Health* 1990; 80:209–210.)

Introduction

Acquired immunodeficiency syndrome (AIDS) was first reported in prison inmates in 1983.[1,2] As of October 1, 1988, 3,136 AIDS cases had been reported in a survey of state and federal correctional facilities.[3] Since inmates frequently report intravenous (IV) drug use both before and during incarceration,[4,5] human immunodeficiency virus (HIV) infection in this population is not surprising. Studies of persons entering prison in the United States have shown rates of HIV seropositivity ranging from 0 to 17 percent.[3,6]

Several state prison systems, including the Nevada Department of Prisons, routinely screen incoming inmates for antibody to HIV. In Nevada, this is mandated by law. In August 1987, the Nevada Department of Prisons also began testing all inmates for antibody to HIV at the time of their release. To estimate how frequently HIV seroconversion occurs after inmates are admitted to a correctional facility and to assess whether seroconversion is the result of HIV exposure while in prison, we surveyed the results of HIV antibody testing of all inmates released from the Nevada Department of Prisons between August 1987 and July 1988.

Methods

The Nevada Department of Prisons operates 14 correctional facilities: one maximum and three medium security facilities for men, one women's facility, seven minimum security facilities, and two transitional centers. All persons admitted to the system beginning August 1985 received HIV antibody testing. In addition, all inmates in the system were tested in a prevalence survey from September through December 1985. Post-test counseling is offered to all inmates tested.

HIV antibody was determined by enzyme immunoassay (EIA; Electronucleonics Inc., Columbia MD, and Abbott Laboratories, Chicago, IL). Repeatedly EIA positive specimens were tested by the Western blot method at the University of California, Davis. Presence of an envelope band and a *gag* or *pol* band were required for Western blot confirmation.

Seropositivity of groups was compared by chi-square analysis. Confidence intervals were calculated using the Taylor series method.

Results

In September through December 1985, 92 (2.4 percent) of the 3,837 inmates* tested were HIV-seropositive. The highest proportion of seropositive inmates was found among Blacks (5.4 percent), females, and those 30 or more years of age (Table 1).

HIV seropositivity in incoming inmates from August 1985 to July 1988 was 124/5,216 (2.4 percent). In the first year of the study, the rate was 43/1,623 (2.6 percent); in year two, it was 43/1,758 (2.5 percent); and in year three, it was 38/1,835 (2.1 percent). No variation in age or race distribution of the affected inmates was seen over time (data not shown).

A total of 1,105 inmates had initial samples obtained on entry or in the prevalence survey and again on leaving the prison system. Of these 1,105 inmates, 1,066 (96.5 percent) were seronegative on initial testing and at exit; 36 (3.3 percent) were seropositive on both tests, two seroconverted, and one inmate was a possible seroconverter (Table 2). The seroconversion rate was therefore 2/1,069 or 0.19 percent of susceptibles. The 1,069 inmates whose initial test was negative were followed a total of 1,207 person-years; the seroconversion rate could therefore also be expressed as one conversion per 604 inmate-years.

To determine whether transmission had occurred within the prison system, we also assessed the HIV serostatus of all inmates in the system during the study period who had

*Racial-ethnic distribution of prison population: White 58.1 percent; Black, 33.3 percent; Hispanic 6.3 percent; Other 2.3 percent.

3	22	M	White	7 days	None known	EIA −	EIA +, WB indeterminate (p24 only)

entered on or before December 31, 1981; 313 such inmates were identified. Fifteen (4.8 percent) of these were HIV seropositive; however, all 15 had had their incarceration interrupted by parole at some time since 1982, and thus might have acquired HIV infection outside the prison.

Discussion

IV drug use has been cited as the major risk behavior for HIV seropositivity among prison inmates.[2,3] Our observation of a higher rate of HIV seropositivity in non-White inmates may therefore be a reflection of higher rates of IV drug use in non-White inmates or of higher rates of HIV infection in non-White IV drug users,[7] or both. The increased rate of HIV infection in incarcerated women in our survey may reflect an increased percentage of incarcerated women who are either IV drug users or sex partners of drug users. In Nevada, incarceration for a drug-related offense is more common among non-White than White inmates (18 percent versus 11 percent) and among female than male inmates (24 percent versus 13 percent); we therefore suspect that increased drug use in these groups accounts for the increased HIV seropositivity (Nevada Department of Prisons, unpublished data). Increased HIV seropositivity in older inmates may be related to duration of high-risk behavior for acquisition of HIV.

The rate of HIV seropositivity in incoming inmates (2.4 percent) remained stable over the three years of our study. Rates in incoming inmates in Maryland, although higher (7.2 percent), have also remained stable during the past three years.[8] The 2.4 percent seropositivity rate in incoming inmates in Nevada is higher than that reported in 20 of 25 prison systems responding to a recent Department of Justice survey.[3] Thus if HIV seroconversion within prisons such as those reported in the Department of Justice survey were occurring at a substantial rate, evidence of such seroconversion would have been seen in our survey.

Two definite cases of seroconversion to HIV were detected, while a third inmate developed only antibody to the HIV *gag* protein, p24, on Western blot. Reactivity to p24 alone is considered an "indeterminate" result but can be indicative of early seroconversion.[9] Because this inmate denied activity which would have put him at risk for HIV infection and refused retesting after his release, he could not be definitively classified.

The seroconversions could have resulted from exposure to HIV either before or after entering a correctional facility; although inmate 1 (Table 2) was in continuous custody for the four months before his first HIV antibody test, seroconversions occurring more than four months after exposure have been reported.[10] The overall rate of seroconversion (one case per 604 person-years) was even lower than the rate of one per 244 inmate-years reported from a study of inmates in the Maryland State Prison system.[6] However, in that study only a self-selected subset of exiting inmates were tested.

Both IV drug use and homosexual intercourse occur in prisons; in a study of inmates in Tennessee, 26 percent reported intravenous drug use and 17 percent reported homosexual activity while in prison.[5] Presumably, needle sharing and homosexual intercourse are also occurring among inmates in the Nevada Department of Prisons facilities. However, such occurrences are apparently not frequent enough between HIV-infected inmates and susceptibles to result in a high rate of HIV transmission. Because exposures could have occurred before entry into the Nevada State Prison System, the seroconversion rates reported here are maximum estimates of the transmission of HIV in prison inmates. We conclude that transmission of HIV among inmates incarcerated by the Nevada Department of Prisons is rare.

Suicide Clusters: An Examination of Age-Specific Effects

MADELYN S. GOULD, PHD, MPH, SYLVAN WALLENSTEIN, PHD, MARJORIE H. KLEINMAN, MS, PATRICK O'CARROLL, MD, MPH, AND JAMES MERCY, PHD

Abstract: The age specificity of time-space clusters of suicide was examined using National Center for Health Statistics data for 1978–84. Significant clustering of suicide occurred primarily among teenagers and young adults, with minimal effect beyond 24 years of age. Clustering was two to four times more common among adolescents and young adults than among other age groups. (*Am J Public Health* 1990; 80:211–212.)

Introduction

Approximately 29,000 people killed themselves in 1985 in the United States.* Suicide is rare before the age of 12, increases dramatically during adolescence, and reaches a peak between ages 20 to 24 at which time the suicide rate plateaus until another increase is witnessed among elderly men. Suicide among teenagers and young adults has increased markedly since 1960, moving suicide from the fifth leading cause of death to the second leading cause of death among teenagers in 1985.*

The recent occurrence of several highly publicized clusters of youth suicides has focused attention on the problem of suicide "epidemics"—unusually high numbers of suicides occurring in a small area and brief time period. Such outbreaks have been reported from ancient times through the twentieth century in diverse populations of varied ages,[1,2] but these reports are difficult to interpret without systematic surveillance and reporting of suicide clusters. Moreover, only recently[3] have statistical techniques for the detection of clusters of suicide in time and space been used, although several studies have examined temporal clustering after suicide stories.[1] Few studies have examined temporal fluctuations, in general[4–7] or spatial patterns.[7] Some clustering of suicides occurs by chance alone, even if suicides are occurring at random, so measurement of the rate of "outbreaks" must account for the clustering expected by chance variation.

Our earlier work indicated that clustering of suicides occurred among 15–19 year olds to a greater extent than would be expected by chance alone.[3] The present report examines the whole life span to determine whether suicide clusters are unique to adolescents or represent a more general phenomenon.

*Mortality Statistics Branch, Division of Vital Statistics, National Center for Health Statistics. Vital Statistics of the United States (Unpublished data for 1985).

Methods

Data Sources

Vital statistics mortality data tapes 1978–84 were obtained from the National Center for Health Statistics (NCHS). Separate analyses were performed for the following age groups: 15–19, 20–24, 25–29, 30–34, 35–44, 45–54, 55–64, and 75+ years.

A suicide was defined as any individual whose cause of death had been listed as codes E950–959 of the Ninth Revision of the International Classification of Diseases (ICD-9). The late effects of a self-inflicted injury (E959) was included in the analyses because the timing of the death, in addition to the initial suicidal act, may influence a subsequent suicide. However, this classification of death only accounted for up to 0.2 percent of the total number of suicides within any age group and, therefore, it is unlikely that it had an impact on the analyses.

Statistical Method

The Knox procedure[8] was used to assess the degree of time-space clustering. Details on alternative procedures and the reasons for selection of the Knox procedure are given elsewhere.[3] The Knox procedure considers all possible pairs of cases and the time and space distances between them. Critical values for time and space to define "closeness" must be specified in advance. The test statistic involves a comparison of the observed number of pairs close in time and space with the expected number, which is the product of the proportion of pairs that are close in time with the number of pairs close in space. The test statistic approximately follows a normal distribution, $Z = (O-E)/\text{variance}$. The variance of the statistic was estimated following the method of David and Barton.[9]

Definition of Cluster

There are no explicit definitions of a "suicide cluster" in the literature. Initial operational definitions and limits for time and space parameters were examined in an exploratory analysis of NCHS data for 15–19 year olds for 1978 and state mortality data for 1978 through 1985, as described elsewhere.[3] Four space units (county and town of residence and occurrence) and five critical time units (3, 7, 14, 30 and 60 days) were examined to define closeness between pairs of cases. Exploratory analyses indicated that county of residence yielded a space unit more sensitive to the definition of a cluster. There was little difference between the five time units in the exploratory examination. The data are reported for 7, 14 and 30 days.

Results

As shown in Table 1, 1,420 close pairs of suicides (same county, 0–7 days) occurred among 15–19 year-olds, whereas 1,339.2 were expected. The 6 percent elevation above chance had an associated p-value of .011. The effect of clustering is primarily observed in the younger age groups (15–19 and 20–24 year olds) at the three critical time units. Very little clustering occurred at older ages, with the exception of the 55–64 year old age group at the seven-day critical time unit.

TABLE 1—Results of Knox Procedure on 1978–1984 NCHS Mortality Detail File

		Window = 7 Days				Window = 14 Days				Window = 30 Days

55–64	25624	6399.6	6623	1.035	.002	13277.2	13401	1.009	.136	28928.5	29260	1.011	.024
65–74	19621	3334.8	3395	1.018	.139	6877.7	6976	1.014	.111	15002.1	15247	1.016	.020
75+	14718	2373.0	2367	0.997	.550	4876.8	4888	1.002	.435	10567.0	10554	.998	.551

The effect size was two to four times greater among the adolescents than in other age groups.

Discussion

Suicide clusters appear to occur primarily among teenagers and young adults, although clusters do occur occasionally at other ages. This is consistent with the findings of Phillips and Carstensen[10]: the impact of suicide stories on subsequent suicides was greatest for teenagers. In addition, although there is no formal surveillance system for suicide clusters in the United States, most of the suicide clusters reported to the Centers for Disease Control have primarily involved adolescents, young adults, or both.[1]

The magnitude of the clustering effect is relatively small, even among teenagers and young adults. Estimates of the percentage of teenage suicides that occur in clusters averages between 1 percent and 2 percent with considerable variation by state and year, yielding a range of estimates from less than 1 percent to 13 percent.[3] However, the relative risk for suicide given exposure to the suicide of one or more other persons may be quite great. Studies at the individual level will be needed to define this relative risk. Moreover, although the number of youth suicides that occur in clusters may be relatively small, they represent a class of suicides that may be particularly preventable. Suicide prevention efforts that focus on high-risk populations is a recommended strategy.[11]

The Centers for Disease Control has recently developed recommendations for a community plan for the prevention and containment of suicide clusters.[12] Targeting multiple risk groups in prevention strategies will be necessary to reduce the suicide rate substantially.

Misclassification of Childhood Homicide on Death Certificates

GARRY D. LAPIDUS, PA-C, MPH, DAVID I. GREGORIO, PHD, MS, AND HOLGER HANSEN, MD, DRPH

Abstract: Suspect classification of homicide deaths of Connecticut residents under 20 years of age was noted for 29 percent of cases examined. Misclassification was attributed to incomplete or erroneous information recorded on the death certificates, rather than errors in the designation of ICD-9 homicide codes. The results have important implications in the interpretation of vital statistics when homicide is listed as the cause of death and underscore the value of record linkage systems. (*Am J Public Health* 1990; 80:213–214.)

Introduction

The causes of death reported on death certificates represent important national, state, and local statistics that are used in epidemiologic research as well as the planning/evaluation of health service delivery.[1,2]

Unfortunately, accuracy of death certificates regarding the cause of death presents problems.[3] In particular, underrecording of childhood homicide is known to be a serious problem.[4] It is thought to occur for a variety of reasons including ascertainment difficulties,[5] reporter unwillingness to consider homicide as a diagnosis,[6] and misclassification of homicides as "accidents" or as "cause of death unknown."[7]

This report addresses a complementary issue: the overrecording of childhood homicides on vital statistics.

Methods

Death certificates for all reported homicides between 1980–85 among Connecticut residents 0–19 years of age (N = 166) were reviewed by the authors. Supplementary information available from the State's Chief Medical Examiner Office on circumstances leading to the death of subjects (i.e., police investigation reports, eyewitness accounts and hospital records, laboratory and autopsy reports) was examined for the 161 deaths which occurred within the state.

The manner of death recorded on the death certificate (unintentional injury, homicide, suicide, or undetermined) was evaluated for consistency with supplementary information obtained from files of the State's chief medical examiners office. Homicide is defined in the ICD-9 CM manual as "injuries inflicted by another persons with intent to injure or kill by any means."[8] This definition is consistent with the legal interpretation of criminal homicide, i.e., "lethal violence (unlawfully) inflicted by a second person (or persons) with the intent to do bodily harm."[9] Non-criminal homicide deaths (i.e., negligence, justifiable homicide),[9] by contrast, would be excluded by a strict application of the ICD definition.

Certificates attributing death to the intentional use of a firearm, stabbing with a sharp instrument, other physical assault, arson and the like, when corroborated with statements by the assailant(s) or other eyewitnesses, and/or information from medical records and police investigations were considered accurate. Typical examples would be: an adolescent's death due to firearm injury where review of the medical examiner's report and police investigation report an argument following alcohol and/or illegal drug use in the company of friends or an acquaintance; a victim under three years of age for which a sworn confession by a parent attributes death to assault by blunt force was considered an appropriate designation of homicide.

Death certificates for which supplementary information was at odds were judged suspect for the purposes of this study. Our decisions were based on whether the police investigation documented criminal intent to injure or kill.

A preliminary review of circumstances leading to the death of cases suggested six causes of death for which an application of the ICD-9-CM homicide definition might be suspect; negligent use of a motor-vehicle, (e.g., motor vehicle/pedestrian collisions, without evidence of intent to injure, but rather hit and run incidents where the legal transgression was leaving the scene of a crash without stopping to give aid), unintended discharge of a firearm, (e.g., play with firearms by children, resulting in the unintended discharge of the weapon), suicide, legal intervention, arson, and drowning (e.g., where intent to harm was not documented).

Results

For 47 of 161 deaths studied (29 percent), we judged the manner of death reported on death certificates not to conform to strict interpretation of the ICD definition of homicide when supplementary information was taken into account. These included: 16 deaths due to arson, 13 motor vehicle pedestrian or pedal cycle collisions, 11 unintentional discharge of a firearm, four legal interventions, two suicides, and one drowning.

Table 1 characterizes those 47 cases. Error (20 percent) was less common regarding cause of death among 15–19 year olds, and most common (65 percent) among 10–14 year olds.

In addition, slight differences were noted by the race and sex of victim. Cause of death was misclassified in 17 of 74 cases among Whites (23 percent) compared to 30 of 87 among others (34 percent). Twenty seven percent of male cases compared to 33 percent of female cases were misclassified.

Discussion

Consistent use of the ICD-9 definition of death was found to be problematic in our investigation. Excluding such deaths from rate calculations would yield a corrected homicide rate of 2.13 per 100,000 persons, a reduction of some 30 percent of the current reported annual homicide rate for this age group.

We recognize the subjective nature of our effort and that additional information on the cases reviewed here (e.g., the legal disposition of criminal charges in such matters) may shed further light on the circumstances of intent to injure.

47 of 161:29%

Furthermore, we recognize that underrecording of childhood homicides (i.e., false-negative cases) likely exceeds the discrepancies noted here. Our analysis focused exclusively on deaths for which the designation of homicide as a cause of death was problematic (i.e., false-positive cases). Attention to the complementary issue (i.e., the designation of criminal homicide deaths as unintentional injury, death due to other causes or cause of death unknown) was beyond our current resources but remains an area requiring further attention.

Our study pointed out several instances of failure to identify the cause of death correctly in circumstances involving the unintended use of firearms (e.g., playing with guns), hit and run motor vehicle collisions, legal intervention by police officers, arson, suicide and drowning. Patterns of misclassification related to the age of victim and mode of injury were detected. However, we were unable to specify systematic biases in the way data were recorded. Misclassification apparently resulted from incomplete or erroneous information on death certificates, rather than errors of ICD-9 homicide coding. Death certificates used for medical examiner cases require listing the manner of death as "accident, homicide, suicide, or undetermined." Presumably, initial homicide determination on the part of the medical examiner when forwarded to the state health department was then "properly" assigned an ICD-9 homicide code.

The importance of maintaining procedures for updating medical examiner files with related information available from police and hospital sources as well as revising death certificates on the basis of supplementary information that may be received is pertinent here. Permanent misclassification of deaths as homicides become more likely as procedures for revising certificates are inconsistent. In several instances we noted incomplete police reports. In others, supplementary information was dated after the certification of death date.

Problems stem, as well, from deficiencies of the ICD-9 classification system which do not allow accurate coding of "hit and run" motor vehicle pedestrian collisions. Roughly one-fourth (27 percent) of misclassified cases (13 of 47) were situations of this type. The coding of such cases as homicide rather than negligent use of a motor vehicle implies criminal intent by drivers. Such certificates provide little information to injury control researchers regarding the true circumstances of the event. Of the 161 cases reviewed only one true vehicular homicide was noted.

The Incidence of *Haemophilus Influenzae* Meningitis in a Midwestern Metropolitan County

RANDY B. RICE, BS, ANNE D. WALLING, MD, AND KEN J. KALLAIL, PHD

Abstract: The incidence of *H. influenzae* meningitis in children under five years of age was monitored during the years 1983–87 by a retrospective study of records from all hospitals serving a metropolitan county in Kansas. The mean annual incidence rate for the five years studied was 26.0 per 100,000. This compares with a mean of 56.0 per 100,000 measured in the same county during 1979–82. (*Am J Public Health* 1990–80:215–216.)

Introduction

Haemophilus influenzae type b (Hib) is the most frequent cause of bacterial meningitis in the United States,[1] accounting for 48.3 percent of all cases of bacterial meningitis[2] and causing an estimated 12,000 episodes of illness annually. Approximately 85 percent of *H. influenzae* meningitis cases occur in children below the age of five years.[1,2] Annual incidence rates show wide variation from 19 to 69 cases per 100,000 children under five years of age.[3] Of the six antigenic types of *H. influenzae*, type b accounts for 95 percent of the cases of meningitis.[4]

The purpose of this study was to describe the epidemiology of *H. influenzae* meningitis in children under age five in a midwestern community for the period 1983–87 and to compare the results with a similar study in the same community covering 1979–82.[5]

Methods

The study involved children residing in Sedgwick County, Kansas. The estimated total county population grew from 378,000 in 1983 to 394,000 in 1987 (Table 1). The number of children in the county under age five was estimated each year by the Metropolitan Long-Range Planning Department and updated by birth, mortality, and migration rates. In the under five population, the numbers of males and females were calculated to be equal and the racial composition was determined as 82 percent White, 11 percent Black, and 7 percent "other."

Hospital records were identified for all cases of *H. influenzae* meningitis in residents of Sedgwick County during the years 1983–87. The study included all hospitals serving the county population. Noncounty residents admitted to these hospitals were excluded from the study on the basis of zip code information. Cases missed by outflow to other medical centers are unlikely as the closest large population centers are more than 150 miles from Wichita. Examination of city/county health department records did not reveal any cases which could have died before hospital admission. Cases were identified by primary or secondary ICD codes and confirmed by culture and gram stain of cerebrospinal fluid.

Besides age-specific incidence rates, the variables measured included race, sex, and seasonal distribution. Data on *H. influenzae* meningitis in children under five years of age were extracted from the earlier investigation[5] which had studied meningeal infection of all etiologies in all age groups.

Results

Forty-one cases, all under age five, were identified. Forty were serologically type b and one was type d. These children accounted for all cases of *H. influenzae* meningitis in the community during the study period. The largest number of cases occurred between 12 and 17 months of age, followed by children younger than 6 months (Figure 1). Estimates of the population at risk were used to calculate annual incidence rates. As shown in Table 1, these ranged from 21.7 to 37.9 per 100,000 with a mean for the five years of 26.0 per 100,000 person-years.

H. influenzae meningitis occurred in 22 males and 19 females which corresponds to incidence rates of 27.9 per 100,000 for boys and 24.1 for girls during the five years studied. Thirty-six cases occurred in White children and five in Black (race-specific incidence rates were 27.8 for White children and 28.8 for Black). There were no cases in the "other" racial group. The differences by sex and by age were not statistically significant.

During the five years of the study, *H. influenzae* meningitis showed a bi-modal distribution with the highest number of cases occurring in late autumn and in the spring. The disease was least common in the summer months May through September.

Two White males with severe symptoms died within 48 hours of hospital admission during the study period. The case-fatality rate was 4.9 percent. The mean hospital stay for nonfatal cases was 12.2 days. At the time of hospital discharge, sequelae were recorded in 24 percent of hospital records. These sequelae included hearing loss, mental retardation, coma, acquired hydrocephalus, and respiratory impairments.

Comparison with Previous Study

Data from the earlier study[5] were recalculated to provide the incidence of *H. influenzae* meningitis in children under

TABLE 1—Incidence of *H. influenzae* Meningitis in Children below the Age of Five Years in Sedgwick County, Kansas

Year	Estimated Total Population	Population <5 Years of Age	Cases *H. influenzae* Meningitis	Hib Incidence in Children <5 years*

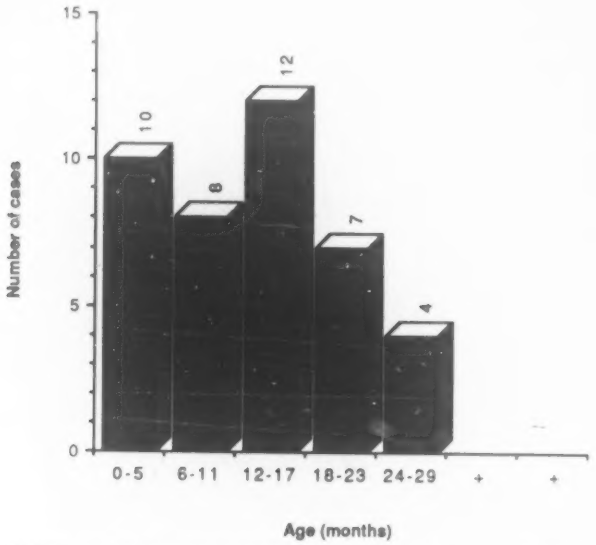

FIGURE 1—The Number of Cases by Age of *H. influenzae* meningitis in Sedgwick County, Kansas during 1983 to 1987

five years of age. The 65 cases observed over the four years (1979–82) corresponded to a mean annual incidence rate of 56 cases per 100,000 children under five, compared to a mean of 26.0 for the five years 1983–87, measured in the present study (95% confidence intervals of difference = 14,36). Methodology was similar for both studies.

Discussion

The assumption that all cases would be admitted to hospital in the county appears valid from our knowledge of clinical practices in the community. Outflow of cases to another city was unlikely as was the possibility of cases being treated without hospital admission. Cases could only have been missed through misdiagnosis and/or miscoding.

The most striking finding is the fall in incidence compared to the previous study. This could be due to several factors such as increased resistance of the population, lowered exposure to *H. influenzae*, decreased virulence of the organism, or the wide variations in annual incidence that occur naturally with this disease.[6] In view of the controversy over vaccination, it is tempting to attribute the fall to vaccination which was introduced to this community in 1986 and is generally offered at 24 months of age. It was not possible to identify data on the proportion of children immunized against *H. influenzae* in the county and information on vaccination was not recorded in the hospital charts. The age of the cases makes widespread immunization unlikely. Immunization could still be responsible for the fall in incidence by reducing cases in older children. This has the dual action of both directly reducing the number of cases and preventing infection being passed to vulnerable younger siblings.

Although the incidence of *H. influenzae* has fallen, the disease remains a potential cause of significant morbidity and mortality. The mortality rate of 4.9 percent confirms that reported by the Federal Centers for Disease Control.[1] One-fourth of all cases had evidence of serious sequelae at discharge and more pathology could be anticipated with long-term follow-up. In addition, the long length of stay represented considerable use of resources. While welcoming the fall in incidence, *H. influenzae* meningitis is a disease which commands respect and continued preventive efforts.

ACKNOWLEDGMENTS

This study was partially funded by the Family Health Foundation of Kansas. It was presented to the North American Primary Care Research Group in San Antonio, TX, April 1989.

Trends in Hospitalized Discharge Rates for Head Injury in Maryland, 1979–86

ELLEN J. MACKENZIE, PHD, SHARON L. EDELSTEIN, SCM, AND JAMES P. FLYNN, MD, MPH

Abstract: Hospital discharge data from all acute care hospitals in Maryland were used to examine trends in hospitalized head injury incidence and outcome by severity. From 1979 to 1986, discharge rates increased by 3.4/100,000 per year; the largest percent increase was for more severe injuries. Discharge rates increased the most for adults ages 15–24 and ages 75+ but declined for children ages 0–4. Coinciding with the increase in head injury discharges was a decrease in the hospital case-fatality rate across all severity groups. (*Am J Public Health* 1990:80:217–219.)

Introduction

The public health importance of head injury as a major source of mortality and morbidity is well recognized. Recent studies have reported incidence rates that range from 152 to 200 per 100,000 population depending on case definitions and case ascertainment methodologies.[1–9] Despite differences in the magnitude of these estimates, findings regarding the patterns of incidence by age, race, sex, and severity are highly consistent. There is only one published report, however, in which these patterns have been examined over time (Olmstead County Minnesota, 1935–1974).[1] This paper describes the incidence of hospitalized head injury in Maryland over the eight-year period 1979–86.

Methods

Data Sources

Incidence rates of hospitalized head injury, 1979–86, were computed for the State of Maryland using uniform hospital discharge abstract data maintained by the State's Health Services Cost Review Commission for all 56 acute care, non-federal, hospitals as mandated by law. Excluded from the database are injuries treated on an outpatient basis as well as deaths that occur at the scene, in transport, or in the Emergency Department. Data abstracted include patient demographics, up to five ICD-9CM coded discharge diagnoses, up to three procedures (ICD-9CM coded), total and ICU length of stay, total and component charges, discharge status, and expected principal source of payment. There is a high degree of confidence in the quality of the discharge abstract data, including the diagnostic information, as they are used in paying all hospitals in the State.

To compute discharge rates the total number of hospital discharges (both residents and non-residents) was divided by the State resident population for that year as estimated by the Maryland Department of Health and Mental Hygiene. This approach assumes that the number of state residents treated in out-of-state hospitals roughly equals the number of non-residents treated in-state. All age-adjusted rates are based on direct adjustment using the 1980 census as the reference population.

Definitions

A head injury case was defined as any discharge with a principal or secondary diagnosis of a skull fracture and/or intracranial injury (ICD-9CM codes 800, 801, 803, 804, 850–854). A secondary head injury discharge was included only if the principal diagnosis was a traumatic injury to another body system; complications (ICD 9CM 958) and late effects (ICD 9CM 905–909) of injuries were excluded.

Injury severity was determined through the use of the software ICDMAP which maps ICD-9CM coded diagnoses into Abbreviated Injury Scale (AIS) scores. Studies have shown that AIS scores derived from ICDMAP are generally lower than those obtained by reviewing the entire medical record.[10] Discharges with more than one head injury diagnosis were classified according to the most severe (highest ICD/AIS score) head injury. Discharges with a head injury of ICD/AIS 1 or 2 are classified as minor, ICD/AIS 3 as moderate, 4 as serious, and 5 as severe.

1986	94.3	23.1	11.8	5.0	134.2

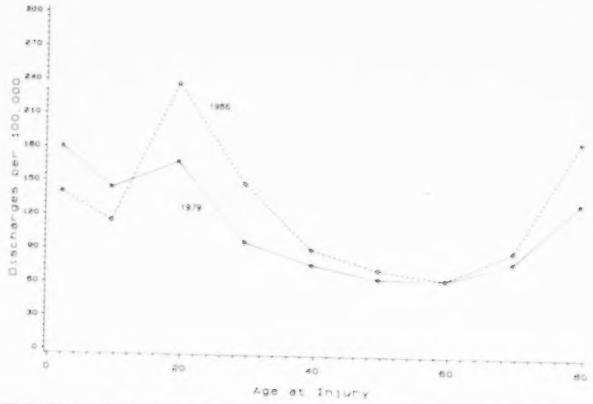

FIGURE 1—Head Injury Discharge Rates (per 100,000) by Age at Injury

Results

Since 1979 there has been an overall increase of 18 percent in the age-adjusted head injury discharge rate from 113.7 to 134.2 per 100,000 (Table 1). A linear regression fit to these data predicted an average increase of 3.4 per 100,000 discharges per year (R^2 = .93). The largest percent increase over the eight-year period was noted among the most severe (ICD/AIS 5) injuries which nearly tripled from 1.7 to 5.0 per 100,000.

Discharge rates for young children ages 0–4 actually declined (180 per 100,000 in 1979 vs 140/100,000 in 1986) whereas rates for adolescents and young adults (ages 15–24) increased (167 vs 236), as did rates among the elderly age 75+ (145 vs 188) (Figure 1). Very little change in discharge rates was noted for adults aged 40–64. The relative risk of age-adjusted head injury discharge rates for males versus females remained relatively constant during the study period with males twice as likely as females to be hospitalized for treatment of a head injury (Table 2). The relative risk for Whites versus others, on the other hand, has declined slightly (1.3 to 1.0).

Hospital case fatality rates have declined between 1979 and 1986 (Table 3) for all severity groups with the greatest relative decrease observed among the moderately severe (ICD/AIS 3) injuries (8 to 5 percent). The percent discharged home has decreased for each severity group while the percent discharged to an extended care facility has increased. This shift in discharge disposition was most notable among individuals with the most severe injuries. Among the ICD/AIS 5 injuries, there was an 8 percent decrease in discharges to home (31 to 23 percent) and a 5 percent decrease in fatality (53 to 48 percent) accompanied by a 15 percent increase (9 to 24 percent) in discharges to an extended care facility.

Discussion

Hospital discharge abstract data generally provide a good source of information on the incidence of injury severe enough to require hospitalization,[9,11,12] and provides readily available population-based data specific to severity. Further, since these databases are maintained over time, they provide the basis for examining temporal trends in incidence.

Since the majority (80 percent) of head injuries in young children were of minor severity, the decrease may reflect changes in admission practices; moreover, in 1983, Children's Hospital in Washington, DC was designated a regional referral center for pediatric trauma, and an increasing proportion of pediatric head injuries occurring in the DC Met-

ropolitan Area may have been triaged there and would not be recorded in the Maryland hospital discharge abstract database. A child restraint law enacted, in 1984 may also have contributed to the decline.[13,14]

The increased use of ICD-9CM coded discharge diagnoses as a basis for hospital payment has been shown to result in more attentive coding which might explain a shift toward more severe injuries among adolescents, young adults, and the elderly.[15] However, Maryland hospitals have been paid under a per-case payment system since the mid 1970s so that changes in coding practices are not likely to have occurred over the study period. The increased availability and use of CT (computed tomography) scans in the early 1980s may account for increased specificity in diagnosis of specific brain lesions which could result in a shift toward higher ICD/AIS scores. However, neither coding practices nor improved diagnostic procedures would likely account for the increase in overall discharge rates.

The increase in discharge rates accompanied by a decline in the hospital care fatality rates may reflect improved emergency medical services, or increased use of seat belts.[16] The increase in hospital discharge rates over the last eight years accompanied by a small decrease in the case fatality rate has resulted in an increase in the number of survivors with head injury severe enough to result in hospitalization. Several studies have documented the nature of sequelae resulting from severe as well as minor head injury.[17–25] As the number of head injury survivors increases, more hospital-based as well as community services aimed at rehabilitating the head-injured individual will be needed.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of Dr. Antoinette De Fazio and Dr. Mark Kelly both of the Montebello Rehabilitation Hospital. The Johns Hopkins Graduate Summer Program in Epidemiology

The Department of Epidemiology of The Johns Hopkins University School of Hygiene and Public Health one of the largest and oldest departments of epidemiology in the United States, proudly sponsors

The Eighth Annual Graduate Summer Program in Epidemiology

June 18 – July 6, 1990

PROGRAM DIRECTOR

Moyses Szklo, M.D., M.P.H., Dr. P.H.

COURSE OFFERINGS

- Applied Multivariate Statistics
- Cancer Risk and Prevention
- Design and Conduct of Clinical Trials
- Epidemiologic Methods for Evaluating Health Services
- Epidemiology and the Law
- Epidemiology of AIDS
- Epidemiology of Mental Disorders, Alcohol and Drug Problems
- Infectious Disease Epidemiology
- Introduction to Biostatistics
- Methods in Epidemiology
- Methods of Health Risk Assessment
- Nutritional Epidemiology
- Principles of Epidemiology
- Use of Microcomputers in Epidemiology

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. The Impact of Legalized Abortion on Adolescent Childbearing in New York City

THEODORE J. JOYCE, PHD, AND NACI H. MOCAN, PHD

Abstract: In this paper we estimate the impact on adolescent childbearing of the liberalization of the New York State abortion law in 1970. Using Box-Jenkins time series techniques to analyze monthly data on the number of births to White and Black adolescents from January 1963 to December 1987, we found that the level of births to Black adolescents living in New York City fell 18.7 percent, approximately 142 fewer births per month, after the law became effective; the level of White births fell 14.1 percent, approximately 111 fewer births per month. Projections based on the fitted model suggest that a ban on legalized abortion today would have a major impact on adolescent childbearing in New York City as well as other parts of the country, although the magnitude of the change would vary according to local conditions. (*Am J Public Health* 1990; 80:273–278.)

Introduction

There has been great speculation in the popular press whether the US Supreme Court will overturn the 1973 decision in *Roe versus Wade*, the case which legalized abortion across the United States. A likely outcome of such a reversal is that the authority to regulate abortion will be given to individual states. To understand how a dramatic shift in the availability of legalized abortion might affect adolescent childbearing, we examined the changes in the number of births to New York City teenagers following the 1970 New York State law which liberalized abortion. It is our contention that the decline in teenage childbearing between 1970 and 1971 is a good approximation, in reverse, to what would occur today if legalized abortion were no longer available.

A number of studies have noted the decline in births after the New York State Law which liberalized abortion became effective.[1–3] However, the results in each of the studies were based on annual changes over a very short time span. Such unrefined estimates provide only a crude understanding of what might occur if the legalization of abortion were reversed. Pooled time-series, cross-sectional studies have examined the effect of liberalized abortion laws on annual, age-specific fertility rates within and across states.[4–6] The findings suggest that the legalization of abortion had an important impact on fertility rates. Again, the variation over time was limited to at most seven years.

Our study differs substantially in that it is a time-series analysis with monthly data that spans 25 years. The large number of observations allows for a more sophisticated means of fitting the data. In particular, we used Box-Jenkins methods to determine the magnitude and statistical significance of the change in adolescent childbearing that followed the liberalization of abortion in New York City in 1970. Based on the fitted model, we estimate the number of unintended births that were averted due to the widespread availability of legalized abortion. The estimates shed light on the changes in adolescent childbearing that would occur if legal abortions were to become unavailable to New York City residents.

Methods

Data

Monthly figures on the number of Black and White live births to New York City residents less than 20 years of age are from vital statistics maintained by the New York City Department of Health. Each year of individual birth records has been aggregated by month for Blacks and Whites separately. The number of birth records with unknown age in any one year was less than .03 percent; those records were deleted from the aggregation. The final series consisted of 300 monthly observations for Whites and Blacks from January 1963 to December 1987. Plots of the race-specific series are shown in Figures 1 and 2.

The analysis was limited to Whites and Blacks because ethnicity was not identified on New York City birth certificates until 1978. However, a substantial proportion of the adolescents who are White are of Hispanic origin or descent. Data from the 1970 Census indicate that 13.4 percent of all women 15 to 19 years of age were of Puerto Rican descent.[7] The number of other Hispanic adolescents in 1970 is not known. By 1980 17.0 percent of adolescents 15 to 19 years of age were Puerto Ricans, while the total proportion of all Hispanic adolescents of the same age stood at 25.9 percent. Moreover, in 1984, the first year in which data on births to Hispanic women were published, 75 percent of the White adolescents who gave birth were of Hispanic origin.[8]

The number of births as opposed to birth rates were analyzed because monthly population figures for New York City were unavailable over the period under study. Census data could have been used to estimate monthly population figures between the census years, but such crude estimates would have introduced measurement error. Furthermore, month-to-month changes in the population are minor compared to the 10 to 20 percent drop in the number of adolescent births that were observed between 1970 and 1971.

Statistical Analysis

Two approaches were used to measure the impact of the 1970 legislation on adolescent childbearing. Both approaches used Box-Jenkins time-series analysis.[9] The first approach fitted an autoregressive integrated moving average (ARIMA) model to the pre-legislation data (January 1963–June 1970). Based on the fitted model, we projected the number of adolescent births that would have been expected after July 1970 had abortion not become legal. The difference between the projected births and the actual births is one estimate of the number of births that were averted by the liberalization of abortion.

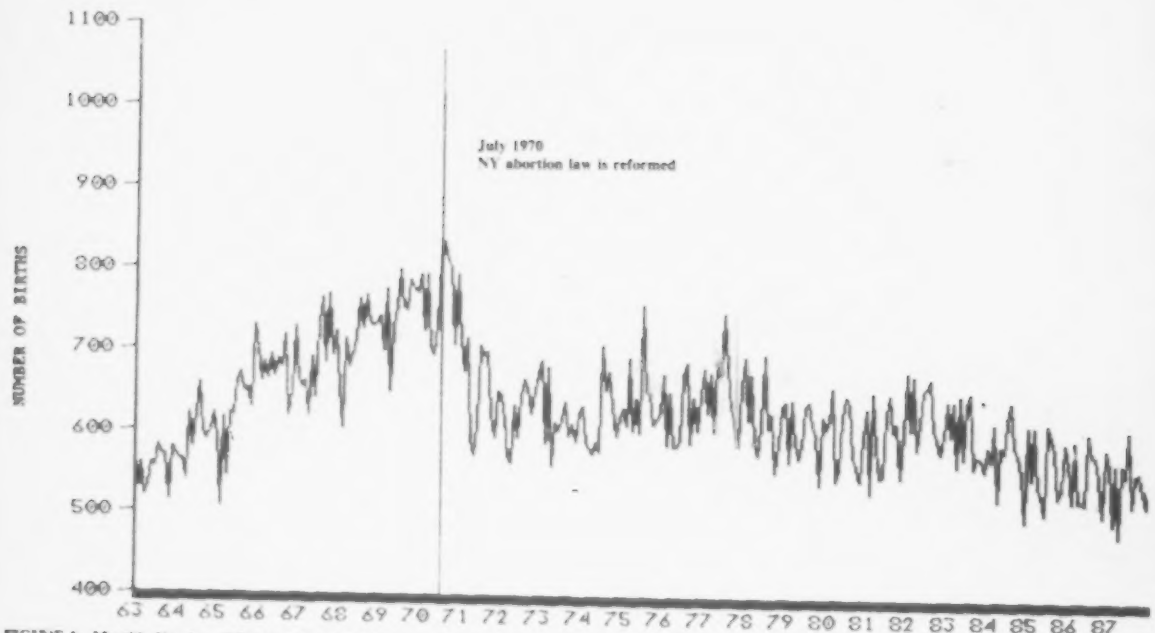

FIGURE 1—Monthly Number of Births to Black Adolescents Living in New York City, January 1963–December 1987

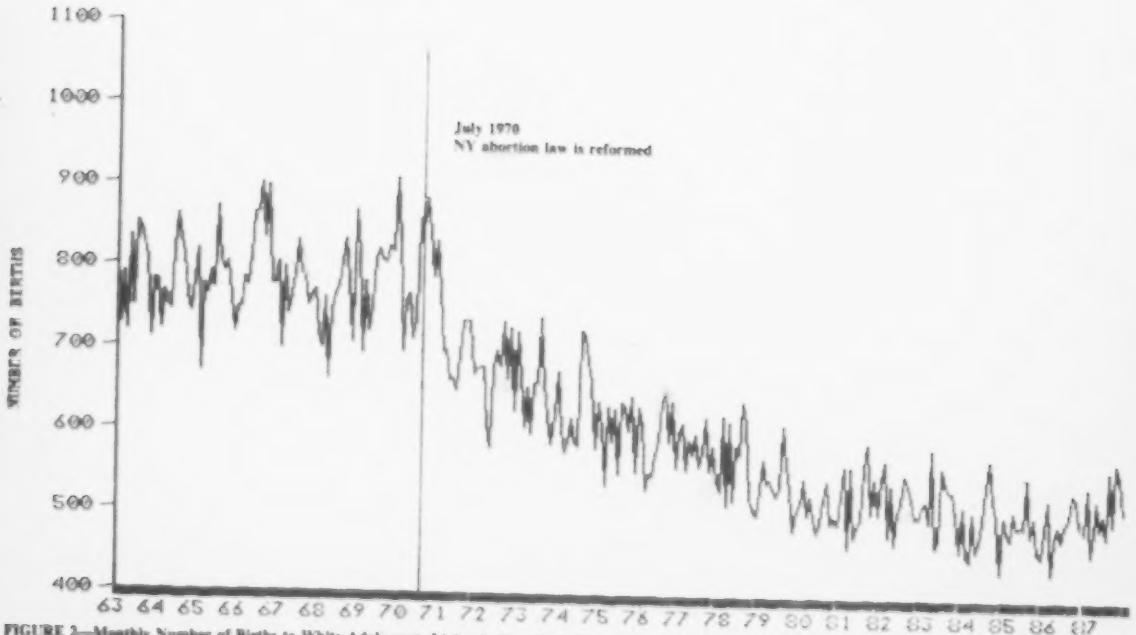

FIGURE 2—Monthly Number of Births to White Adolescents Living in New York City, January 1963–December 1987

The second approach used intervention analysis, an extension of the Box-Jenkins methodology, with the entire data set (January 1963–December 1987).[10,11] The coefficient of the intervention component measures the change in the monthly level of births between the pre- and post-intervention series. The advantage of the intervention analysis is that it is a straightforward means of determining whether the change in the series was statistically significant. Another advantage is that the magnitude of the change is based on a fitted model from observed data over the entire range of the series. The first approach is based on projections generated by the pre-intervention data only. The advantage of the first approach is that if the data were trending prior to the intervention, then the projections would incorporate the trend. The implications of the differences between the two approaches are discussed below.

To successfully apply intervention analysis, it is necessary to know the starting point of the event as well as the general shape of the response of the series to the event. The hypothesis maintained in this study is that the 1970 New York State Law which liberalized abortion had an important impact on the number of adolescent pregnancies that resulted in live births. The law became effective on July 1, 1970. However, because the law did not apply to pregnancies greater than 24 weeks, the effect of the law on the number of live births would not be observed for at least 16 to 20 weeks later. Thus, November 1970 became the starting point of the intervention. Furthermore, the full impact of the law on births to adolescents would not be realized until April 1971 when the pregnancies of the first cohort of adolescents who conceived on or after July 1, 1970 reached term. Consequently, the intervention variable was specified in such a manner that the law's impact on the number of adolescent births increased gradually from November 1970 through April 1971.

The rate at which the law's impact grew between November and April was based on the distribution of abortions by gestational age to New York City residents the first year the law was in effect. For example, 6.1 percent of all abortions to New York City residents were to women whose pregnancies were beyond the twentieth week.[2] Assuming the distribution of abortion by gestational age was the same for every month in the first year,the proportion of the law's full impact that would be felt in November was .061. Thirty percent of all abortions performed in the first year were to women whose pregnancies were between 13 and 20 weeks gestation. We assumed that 15 percent were performed between 13 and 16 weeks gestation, and the other 15 percent were performed between 17 and 20 weeks gestation. Thus, in December, the proportion of the law's full impact would be .216. This accounts for the 6.1 percent of the women who aborted in August 1970 whose pregnancies were greater than 20 weeks gestation and for the 15 percent of the abortions in July 1970 to women whose pregnancies were between 17 and 20 weeks gestation. Following this algorithm and noting that 64 percent of all abortions were performed in the first trimester, the figures for the remaining months were as follows: .361 in January, .574 in February, .785 in March, and 1.0 in April and all months thereafter.

Results

Figures 1 and 2 present the monthly number of births to Black and White New York City adolescents from January 1963 through December 1987. For Blacks, the reversal of a seven-year upward trend between 1970 and 1971 is dramatic. In the case of Whites, a relatively stationary series up to 1970 falls substantially between 1970 and 1971 and then continues downward until approximately 1986. Both figures suggest a major alteration in adolescent childbearing that is coincident with New York State's liberalized abortion law which became effective July 1970.

The ARIMA specification for the pre-intervention series is presented in Table 1. The data are expressed as natural logarithms in order to control for non-stationarity in the variance. A first-order difference transformation was applied to the logarithms of births in order to remove any trend; a twelfth-order difference was used to eliminate seasonality. Based on the autocorrelation and partial autocorrelation functions of the transformed series, Black and White births can be characterized as a first-order moving average with a first-order seasonal moving average. The coefficients of the models are displayed in Table 1. The Q-statistics in Table 1 indicate that the residuals from the estimated models are "white noise" (random variation) processes.[12] Another approach for determining if the errors are "white noise" is to test whether the first difference of the residuals follows a first-order moving-average process with the moving-average parameter equal to 1, and the first autocorrelation equal to −.5. For both Blacks and Whites this was confirmed (results not shown).

Based on the fitted model in Table 1, we projected the number of race-specific adolescent births 24 months beyond June 1970. The projections assume that abortion was not liberalized. A comparison of the actual number of births to the projected number of births is presented in Figures 3 and 4. Subtracting the actual number of births from the projected number and summing over the 24 months indicate that 4,091 Black births and 3,128 White births were averted by the legalization of abortion over the initial two-year period under the law. Note these figures include the months immediately following the new law in which the change in adolescent childbearing was relatively minor. If one estimates the *monthly* number of averted births based on the first year over which the liberalization realized its full impact (April 1971 through March 1972) then 226 Black births and 178 White births were averted per month.

To more formally test whether the 1970 law liberalizing abortion may have caused the precipitous drop in adolescent births, we used all the data to re-estimate the ARIMA structure of each series. As outlined in the previous section, an additional variable was added to the specification to

TABLE 1—Estimated ARIMA Equations for NYC Births to Black and White Adolescents: 1964–1970

BLACKS	θ_1	Θ_1	Q*(24)	R^2
$B_t = -\theta_1 e_{t-1} - \Theta_1 e_{t-12} + e_t$	.735 (9.16)	.801 (9.24)	15.01 .92	.63
WHITES	θ_1	Θ_1	Q(24)	R^2
$W_t = -\theta_1 e_{t-1} - \Theta_1 e_{t-12} + e_t$	.772 (9.38)	.644 (5.70)	19.41 .73	.56

B_t and W_t are the natural logarithms of the Black and White births respectively. θ_1 and Θ_1 are the coefficients and e_{t-1} is the error term. The numbers in parentheses are the t-ratios.
*The Ljung-Box Q statistic determines the randomness in autocorrelations of residual errors, and has a Chi-square distribution.[12] The numbers below the Q-statistics are the marginal significance levels, i.e., the probabilities of the null hypothesis that the autocorrelations of the errors are not different from zero.

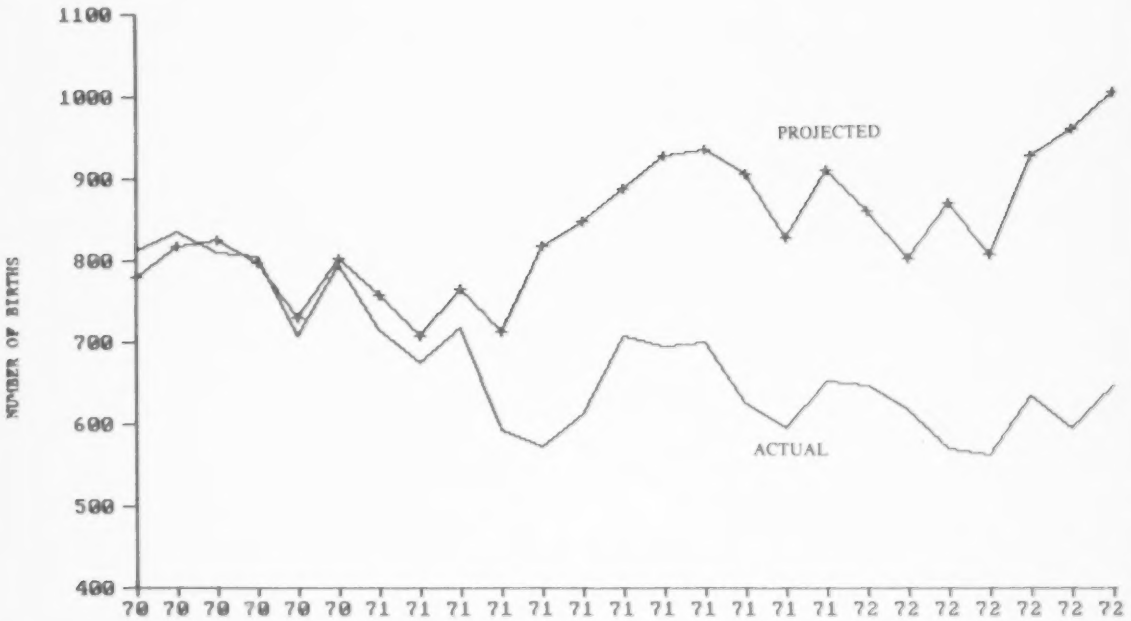

FIGURE 3—Monthly Number of Actual and Projected Births to Black Adolescents Living in New York City, July 1970–July 1972

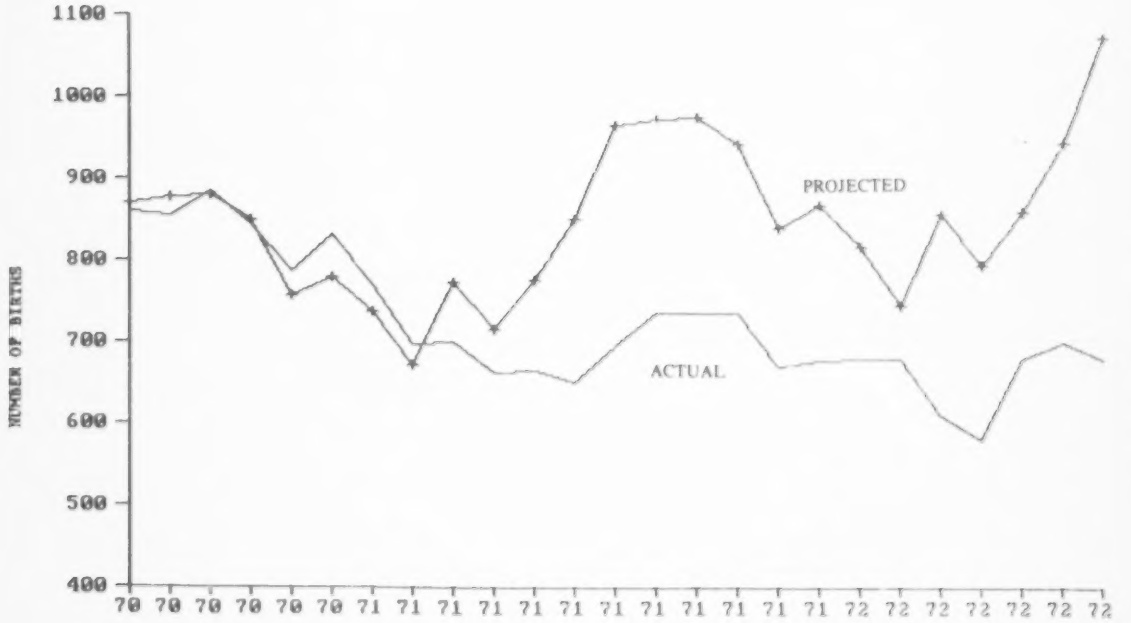

FIGURE 4—Monthly Number of Actual and Projected Births to White Adolescents Living in New York City, July 1970–July 1972

control for the impact of the law. The results are shown in Table 2. Except for the intervention component, the ARIMA structure is unchanged for Blacks. In the case of Whites, a second-order seasonal moving-average component improved the model's fit. The coefficient of the intervention variable, α, is statistically significant for Blacks and Whites. Thus, the data reveal that the decline in the level of births after October 1970 was a change that could not be explained by the normal variation in the series.

The magnitude of the change from the pre- to post-intervention level of the series can be obtained by exponentiating the coefficient on the intervention variable, α, and subtracting it from one. Expressed as a percentage, the level of Black adolescent births fell 18.7 percent after the liberalization of abortion in July 1970 (95% confidence interval = 25–12). White births fell 14.0 percent (95% CI = 20–8). If we use the average number of births over the 12 months prior to July 1970 as an estimate of the pre-intervention level of births, then 2,588 Black adolescent births and 1,998 White adolescent births were averted in the 24 months after July 1970. If the number of averted births is estimated over the first 12 months in which the law's full impact was realized (April 1971–March 1972), then 142 Black births and 111 White births were averted per month.

Discussion

Using monthly data on the number of White and Black births to New York City adolescents, we found that the liberalization of the New York State abortion law in 1970 had a substantial impact on adolescent childbearing. We also found that Blacks were more affected than Whites by the liberalization of abortion. The finding suggests that Whites may have had more access to illegal abortions than Blacks prior to the liberalization.

We used two approaches to estimate the number of births that were averted by the widespread availability of legalized abortion. We consider the estimates obtained from the intervention analysis to be conservative estimates for they do not take into account the upward trend in the number of births especially among Blacks prior to the 1970 liberalization (see Figure 1). The advantage of these estimates is that the level of births from which the changes are estimated is based on actual, as opposed to projected, data. The estimated number of averted births that were obtained by subtracting the actual number of births from the projected number of births should be viewed with some caution. Although they incorporate underlying trends, the projections are based on only seven years of data.

Finally, it should be noted that the decline in births to adolescents in the two years after July 1970 would not necessarily lead to a decline in completed fertility if the teenagers having abortions simply delayed their childbearing until a later age. However, the evidence to date indicates that early childbearers have more children and more unwanted children than women who delay childbearing.[13]

The analysis was limited to New York City because of the special circumstances surrounding the liberalization of New York abortion laws in 1970. Prior to the change in 1970, pregnant adolescents had essentially no access to legal abortion. Although Hawaii, Alaska, and Washington State has laws similar to New York's by the end of 1970, each state had residency requirements. Consequently, the magnitude of the change in adolescent childbearing among New York City residents after the 1970 law became effective was not diminished by migration to other states. The same was not true for residents of other states after the passage of the New York State law. Between July 1970 and June 1971, 75.4 percent of the 33,964 abortions performed on adolescents in New York City were to out-of-state residents.[2]

To gain some insight into the impact on teenage childbearing if legal abortion were unavailable to New York City residents, we applied the coefficients on the intervention variable in Table 2 to the projected number of births in 1988 and 1989. We adjusted for the gradual impact of a ban by the gestational age distribution of abortions prevailing today. If legal abortion were banned January 1, 1988 there would have been 2,618 (18.7 percent) additional Black births and 1,223 (14.0 percent) White births to New York City adolescents in 1988 and 1989 above what would have been expected had the laws regarding abortion remained unchanged.*

The projections are based on a number of assumptions that should be made explicit. First, we assume that the reversal of *Roe versus Wade* would result in a nationwide ban of legalized abortion. Although such an outcome is unlikely, the projections remain instructive because they provide upper-bound estimates based on the most restrictive scenario possible. This scenario cannot be dismissed lightly given that President George Bush, US Attorney General Richard Thornburgh, and Health and Human Services Secretary Louis Sullivan have publicly stated their opposition to *Roe versus Wade*.

A more likely scenario if *Roe versus Wade* were overturned is that New York State will continue to permit legalized abortion. New York is one of only 13 states plus the District of Columbia that currently funds abortions to Medicaid-eligible women and one of only eight states that does so voluntarily.[14] Nevertheless, New York's 1970 law passed the State Senate by five votes and the State Assembly by only one. The debate in both houses was tumultuous.[15]

A second assumption upon which the projections are based is that the use of abortion by adolescents in the early 1970s is unchanged. In fact, the percentage of pregnancies (live births plus induced abortions) terminated by induced abortion has risen from 40.2 percent for Whites and 47.1

TABLE 2—Estimated ARIMA Equations for NYC Births to Black and White Adolescents with the Intervention Component 1964–1987

BLACKS $B_t = -\theta_1 e_{t-1} - \Theta_1 e_{t-12} + e_t + \alpha I_t$

θ_1	Θ_1	α	Q*(48)	R^2
.776	.838	−.207	34.20	.64
(20.68)	(24.87)	(−5.32)	.93	

WHITES $W_t = -\theta_1 e_{t-1} - \Theta_1 e_{t-12} - \Theta_2 e_{t-24} + e_t + \alpha I_t$

θ_1	Θ_1	Θ_2	α	Q(48)	R^2
.824	.740	.122	−.150	42.16	.61
(23.94)	(12.04)	(1.95)	(−4.10)	.71	

B_t and W_t are the natural logarithms of the Black and White births respectively. θ_1 and Θ_1 are the coefficients and e_{t-1} is the error term. I_t is the dummy variable for the intervention; α is its coefficient. The numbers in the parentheses are the t-ratios.

*The Ljung-Box Q statistic determines the randomness in autocorrelations of residual errors, and has a Chi-square distribution.[12] The numbers below the Q-statistics are the marginal significance levels; i.e., the probabilities of the null hypothesis that the autocorrelations of the errors are not different from zero.

*A detailed description of how the projections were obtained is reported in the National Bureau of Economic Research Working Paper No. 3002 by the authors.

percent for Blacks in 1972 to 54.8 and 59.2 percent, respectively, in 1986.** In this respect, our projections may underestimate the impact of a ban on legalized abortion.

One explanation for the increased use of abortion by adolescents is that the availability of abortion has engendered less effective contraceptive behavior; the more extreme version is that abortion has served as an alternative method of fertility control. Thus, if abortion were banned, the pregnancy rate may fall because of better contraceptive behavior. There is no evidence to support either explanation. A 1982 survey reported that only 0.4 percent of women at risk of an unintended pregnancy but using no contraception admitted doing so because they relied on abortion.[16] And although little is known about the relationship between abortion availability and the effective use of contraceptives, a teenager who aborted a pregnancy was less likely to become pregnant again over the next 24 months than was a comparable adolescent who carried her first pregnancy to term.[17]

As noted above, the proportion of births to White adolescents of Hispanic descent is substantial. Based on the little data that exists, Hispanic adolescents are more sexually active than their White counterparts who are not Hispanic. At the same time, Hispanic adolescents are more likely to be married and less likely to abort.[18,19] To the extent these tendencies offset each other, the proportion of Hispanics adolescents at risk of an unintended pregnancy may be similar to that of other Whites.

There is a voluminous literature on the social and economic consequences of adolescent childbearing. As the most recent and comprehensive review makes clear, adolescents who become parents will complete less schooling, have lower wages, experience greater marital instability, and be more dependent on welfare programs than their adolescent peers who delay childbearing.[13,18] Moreover, the children of teenage mothers will experience greater health, cognitive, and socioemotional difficulties.

Nor would a ban on legalized abortion be costless to taxpayers. In 1986, 64.6 percent of all adolescent births in New York City were funded by Medicaid.[20] Assuming Medicaid eligibility is a good proxy for AFDC (aid to families with dependent children) eligibility, then applying this proportion to the number of unintended births reported above indicates that 790 White and 1,691 Black teenage mothers and their children will receive AFDC in the two years after the ban. Based on the methodology described by Burt,[21] the present discounted cost in terms of Medicaid, AFDC, and food stamps of supporting a family headed by a teenager over a 20 year period is $5,560 in 1985 dollars above what it would have cost to support the same teenager and her family had she delayed childbearing until after she was 20 years of age.[21] Thus, the total marginal costs of supporting the 790 White and 1,691 Black births described above would be $13.8 million.

The percentage changes in adolescent childbearing among Whites and Blacks following a prohibition of legal abortion are clearly speculative and cannot be applied to other parts of the country because the projections are based on a set of circumstances specific to New York City in 1970. However, the number of unintended pregnancies among US adolescents strongly suggests that areas in which legal abortion is prohibited will experience substantial increases in the number of births to teenagers. The magnitude of the change will vary by area because of differences in the use of abortion prior to a ban, the proximity to areas where abortion remains legal, and the availability of illegal abortions.

**The figures are based on data provided by the New York City Department of Health.

An Evaluation of External Cause-of-Injury Codes Using Hospital Records from the Indian Health Service, 1985

SUZANNE M. SMITH, MD, LEWIS S. COLWELL, JR., BS, AND JOSEPH E. SNIEZEK, MD, MPH

Abstract: To evaluate the usefulness of International Classification of Diseases external cause-of-injury and poisoning codes (E codes) for public health surveillance of nonfatal injuries, we analyzed E codes from Indian Health Service (IHS) hospital records. E codes for unknown or unspecified causes were used for 25 percent of records. At two hospitals, 63 percent of E codes assigned by independent coders agreed; another 18 percent matched on general cause-of-injury groups. With uniform guidelines and increased training, E coding could provide a valuable, cost-effective method of quantifying and characterizing severe, nonfatal injuries. (*Am J Public Health* 1990; 80:279–281.)

Introduction

Because external causes of injury and poisoning are routinely coded on death certificates under the International Classification of Diseases (ICD) external cause-of-injury and poisoning coding scheme (E codes),[1] we have learned a great deal about fatal injuries. We know much less, however, about the causes of the many more numerous nonfatal injuries, partially because we lack the appropriate data. Although hospital discharge records provide a potential mechanism for public health surveillance of nonfatal injuries severe enough to require hospitalization, most hospitals do not routinely E code discharge data. Recently, influential health policy and advisory groups, including the National Academy of Sciences and the Council of State and Territorial Epidemiologists, have advocated routine E coding of hospital discharge data to link injury data collection and the development and implementation of intervention strategies.[2–4]

Presently, population-based E coded hospital discharge data are already available in the Indian Health Service (IHS). To examine a practical application of hospital discharge data E coding as well as the strengths and limitations of using E codes for injury surveillance, we analyzed IHS records to determine the level and quality of E coding, the reliability of E codes assigned by different coders, and the feasibility of using E coded hospital discharge data as an injury surveillance tool.

Methods

Discharge records for eligible American Indians and Alaska Natives hospitalized at IHS facilities from October 1, 1984—September 30, 1985, were selected for analysis. We excluded records for medical care provided by outside contractors and at tribal facilities (27.9 percent of admissions[5]) because they are not reliably E coded.

Medical records for all hospitalizations were coded by on-site medical records personnel at each of 46 IHS hospitals using the standard ICD (ninth revision)-Clinical Modification (ICD-9-CM)[6] codes and rules. Records were coded after discharge based on clinical assessment, diagnostic and therapeutic procedures, and other health services information collected during the hospitalization and recorded on the chart. Each IHS record was coded for: 1) up to six clinical codes; and 2) one cause-of-injury code, if the hospitalization was injury-related.

The ICD hospital indexing system includes the Classification of Diseases and Injuries (often called "N codes"); two supplementary classifications: Factors Influencing Health Status and Contact with Health Service (V codes*) and External Causes of Injury and Poisoning (E codes); and four appendices (Morphology of Neoplasms, Glossary of Mental Disorders, Classification of Drugs, and Classification of Industrial Accidents). Diagnostic and therapeutic procedures are coded with yet another classification scheme, the Classification of Procedures in Medicine.

The cause-of-injury/poisoning E code has several components. All E codes have three digits following an "E." Three-digit E codes can be grouped according to general external cause or intent (e.g., E880-E888: accidental** falls, E950–E959: suicide and self-inflicted injury). Most three-digit E codes also require a fourth digit subdivision (EXXX.0–EXXX.9) to identify the role of the injured person or to provide additional cause-specific information.

For this analysis, we selected injury records by two independent methods: 1) records with injury and poisoning diagnosis and health services codes (ICD-9-CM codes 800–999 and V71.3–V71.6); and 2) records receiving cause-of-injury E codes (E800–E999). We then compared the files to measure the level of injury coding. To evaluate the reliability of IHS E codes, we reviewed E coded records for two hospitals, abstracted cause-of-injury information, and recoded the external causes of injury and poisoning. The author (SMS) who recoded records was blinded to the original codes.

Results

Of the 10,921 (13.9 percent) IHS hospital discharge records with at least one injury-related diagnosis or health services code, 99.3 percent were E coded. All records with an injury diagnosis code (800–999) had an associated E code;

Smith, MD, Medical Epidemiologist, Program Surveillance Section, Division of Injury Epidemiology and Control, Center for Environmental Health and Injury Control, Mail Stop F36, Centers for Disease Control, Atlanta, GA 30333. Dr. Sniezek is a Medical Epidemiologist, also with that Division at CDC. Mr. Colwell is an Environmental Consultant with the Indian Health Service, US Public Health Service, assigned to the Division of Injury Epidemiology and Control, CDC, both also in Atlanta. This paper, submitted to the Journal March 24, 1989, was revised and accepted for publication July 17, 1989.

*V codes are used for occasions when a person encounters the health care system for a specific purpose other than illness or injury (e.g., immunization or pregnancy). For injuries, certain V codes may be appropriate for persons hospitalized for observation following a traumatic event.

**Although use of the term "accidental" denotes an unpreventable event and, therefore, is to be avoided, unintentional injuries are labeled "accidental" in the ICD.

52 of 128 records selected by an injury health services codes (V71.3–V71.6) were E coded.

Of the 11,063 E coded records selected independent of diagnosis codes, 10,845 (98.0 percent) had at least one injury or poisoning diagnosis or health services code. For the other 218 E-coded records, the most frequent conditions requiring hospitalization were adverse effects of medical/surgical care (N = 106) and poisoning (N = 9). These 11,063 hospitalizations were required for 9,555 individuals.

More than 75 percent of all injury hospitalizations were in six broad external cause groups: transport-related incidents, falls, acts of violence, adverse effects of medical and surgical care, other accidents (being struck, caught, or cut), and suicides/attempts (Table 1). Transport-related events and falls together accounted for more than a third of all injury hospitalizations.

About 25 percent of IHS injury hospitalization records were coded using three-digit E codes for general or unspecified causes of injury, reflecting a lack of more detailed information about the injury events. Most frequently, records for falls, transport-related injuries, and assaults could be coded with only general E codes. For 540 records, the underlying cause of injury was not available, and coders used two non-specific codes, E887 (fracture, cause unspecified) and E928 (other and unspecified environmental and accidental causes).

Fourth-digit codes were assigned where appropriate. Coders assigned a fourth-digit code to all three-digits E codes requiring the additional character. For those three-digit E codes without an associated fourth-digit, IHS appropriately did not assign a fourth digit. For 22.6 percent of records with E codes requiring a fourth digit, a nonspecific fourth digit code was assigned because sufficient information to code the fourth digit was not provided in the record.

The E coding reliability evaluation was based on injury hospitalization records from two IHS Service Units. Ninety-seven percent of 333 discharge records receiving E codes were available to abstract and recode. We assessed coding agreement on a hierarchical scale. When we compared recoded E codes with those assigned by IHS medical records personnel, 59 percent agreed completely (agreement to the three-digit level and agreement to the four-digit level where appropriate). Comparison of the three-digit agreement hierarchy is shown in Table 2. Overall, in 63 percent of the records, the original and recoded three-digit E codes matched. Eighty-one percent of records had matching three-digit codes or similar codes from an external cause group. An additional 5 percent of records had original and recoded E codes that fell under the same ICD-9-CM rubric of intent (i.e., unintentional, intentional, or unknown intent of injury). Neither three-digit E code, external cause group, nor intent agreed for 14 percent of records. For most of the nonmatching sets of codes, medical care providers recorded different scenarios of the injury event on an individual chart or E codes were selected on the basis of recorded injury event circumstances that did not fit well within the ICD-9-CM classification scheme (e.g., Should a fall out of an automobile be coded as a fall or as a transport-related event?).

TABLE 1—Frequency of Three-Digit External Cause-of-Injury Codes from Hospitalization Records,* by Injury Group, Indian Health Service, Fiscal Year 1985

E Codes	External Cause Group	Frequency	Percent	Cumulative Percent
E800–E848	Transport-related	1896	17.1	17.1
E880–E888	Falls	1871	16.9	34.1
E960–E978,E990–E999	Assaults/legal/war	1606	14.5	48.6
E870–E879,E930–E949	Adverse effects of care	1367	12.4	60.9
E916–E920	Struck/caught/cut	973	8.8	69.7
E950–E959	Suicides/attempts	805	7.3	77.0
E980–E989	Intent unknown	477	4.3	81.3
E900–E909	Environmental	456	4.1	85.4
E928–E929	Other/late effects	455	4.1	89.5
E850–E869	Poisonings	366	3.3	92.9
E927	Overexertion	221	2.0	94.8
All Other E Codes		570	5.2	100.0

*N = 11,063

TABLE 2—Percent Agreement of External Cause-of-Injury Codes for Injury Hospitalization Records, Indian Health Service

Level of Agreement	Percent Agreement*		
	Service Unit A (N = 240)	Service Unit B (N = 83)	Cumulative Percent (N = 323)
Three-digit E code	60	71	63
External cause group	76	91	81
Intent**	83	92	86

*A mutually exclusive hierarchy. For each hospital record, the E code assigned by IHS medical records personnel was compared to the E code assigned by one of the authors. Codes matching on the external cause group are those for which both coders assigned three-digit E codes from the same group of external causes (e.g., transport-related incident [E800–E848], falls [E880–E888], or assaults [E960–E978]) but did not assign identical three-digit E codes.

**Codes matching on intent are those for which both coders assigned E codes of the same intent classification (i.e., unintentional, intentional, or unknown intent) but did not assign identical three-digit E codes or codes from the same external cause group.

Discussion

Because proposals to require universal E coding of hospital discharge data are gaining prominence,[2–4,7,8] this examination of E code use in the IHS is valuable for public health practitioners and other researchers interested in injury surveillance and data collection. Few other opportunities exist for us to test the feasibility of requiring universal E coding and to understand the strengths and limitations of injury cause information obtained from E coded records. As shown in this evaluation, routine E coding of IHS hospital discharge data was a valuable, cost-effective method of quantifying and characterizing severe, nonfatal injuries. E codes provided us with a clear distribution of the underlying causes of injuries requiring hospitalization in this population, thus permitting us to identify priority injury problems. Community-based injury prevention programs, based in part on external cause information extracted from hospital records, are currently being coordinated and conducted by trained injury prevention professionals throughout IHS.[9] The E coded records are also valuable for evaluating the effectiveness of these prevention programs.

E codes were reproducible. Although the specific three- and four-digit codes assigned by independent coders sometimes differed, codes agreed closely according to the external cause group. The extent of E coding agreement compares favorably with previous evaluations of the reliability of death certificate and cancer registry information. In Connecticut, an analysis of autopsy reports and corresponding death certificates found major disagreement leading to reclassification of the underlying cause of death for 29 percent of

deaths.[10] For an additional 26 percent of deaths, the death certificate and autopsy report agreed on the major disease category but attributed the death to a different specific disease. As part of the Third National Cancer Survey, death certificates for 48,826 cases of single primary cancer were compared to hospital diagnoses.[11] The underlying cause of death was found to be accurate in 65 percent of cases. In a comparison of data collected from interviews and those reported to the Missouri cancer registry,[12] 70 percent of occupation, 72 percent of industry, 83 percent of smoking status, and 65 percent of alcohol consumption codes agreed. In spite of these limitations, coded data from death certificates and cancer registries have been used extensively in public health practice. E coded hospital discharge data can be of similar value.

With increased attention to the value of E codes, reliability can be improved. E code users and potential users would benefit from standardized E coding guidelines and definitions, increased availability of E code training, and more rigorous evaluation of the current E code scheme. For example, because only 40.6 percent of hospitalizations for observation following trauma (V71.3–V71.6) received E codes in this analysis, we assume that the use of E codes for records coded with health services codes (V codes), and perhaps other injury codes, was not consistent. Due to reimbursement, hospitals have financial incentives to provide adequate training for coders to ensure accurate diagnosis and procedure coding. As more states require E coding of uniform hospital discharge data,[7] the need for uniform E coding procedures and training will increase.

About a fourth of IHS injury records were coded with E codes for general or unspecified external causes. These general or unspecified codes are much less useful for public health surveillance and the development of injury prevention programs. The nonspecific E codes were used most often because more detailed cause-of-injury information was not recorded in the medical charts. Medical record keeping is, understandably, focused on recording clinical assessment and treatment. Generally, health care providers are not aware of the other ongoing or potential uses for medical record data or of the priority data items to collect for public health surveillance. By presenting studies such as this one, health care providers can be made more aware of the crucial role of the medical record in the flow of data through epidemiologic and statistical processes to health care policy development and evaluation.

Because almost all IHS discharge records with injury diagnosis codes received E codes (including multiple injury-related hospitalizations for individuals in the same fiscal year), these E coded records do not represent injury incidence. We could not determine whether the multiple admissions for individuals were due to multiple injury events or follow-up medical and surgical care for previous injuries. E codes could describe injury incidence, however, if coding rules were standardized, restricting E codes to the initial hospitalization following an injury, or if they were modified to include a separate code identifying the initial hospitalization. We could then code records for subsequent hospitalizations consistently using the existing diagnosis codes available for follow-up treatment and late effects of injuries.

Although E coded hospital discharge data have great value for injury surveillance, they have more limited value for epidemiologic research. E codes can help us meet some of the priority objectives for public health surveillance—ascertaining cases, quantifying and characterizing injuries, and monitoring trends in a defined community.[10] Because the number of E codes for certain specific injury events is restricted or absent, the detail needed for focused epidemiologic research is limited. To obtain more detailed cause-of-injury data or information about specific injury problems of interest (e.g., injuries associated with all-terrain vehicles) we will require other surveillance tools or analytic epidemiologic research.

Information about underlying causes is essential for the development, implementation, and evaluation of injury intervention strategies. E coding of hospital records, as performed in the IHS, provides much of this underlying cause information. By extending hospital record E coding to other health care systems, we can develop a standardized external cause data base for prevention programs.

Cardiovascular Deaths among Alaskan Natives, 1980–86

JOHN P. MIDDAUGH, MD

Abstract: Average annual, age-adjusted death rates from cardiovascular diseases and atherosclerosis from 1980–86 among Alaskan Natives were lower than rates among other Alaskans (162.0 vs 242.1; RR = 0.67), while death rates from other causes were higher (954.4 vs 618.6; RR = 1.54). These suggest that Alaskan Natives have less cardiovascular disease than other populations. Additional research on the role of marine omega-3 fatty acids is needed. (*Am J Public Health* 1990; 80:282–285.)

Introduction

Numerous reviews on the role of diets rich in omega-3 fatty acids and the incidence of atherosclerosis and coronary artery disease recently have been published, reflecting widespread interest and enthusiasm over the potential beneficial health effects of omega-3 fatty acid consumption.[1–13]

Careful review of published literature reveals that the epidemiologic studies that show a low incidence of atherosclerosis and cardiovascular disease in arctic peoples, particularly, rest on fragile evidence.[6–9,14,15] For example, earlier works in Alaska to investigate causes of deaths were based on a limited number of autopsies conducted by non-pathologists using no standardized protocols without histopathology, and the two studies reached opposite conclusions about incidence of atherosclerosis among Alaskan Natives.[8,9] A study of death records for 1955–65 found lower mortality rates from heart disease among Alaskan Natives than the US population.[15] This study presents additional data based on death certificates on the causes of death among Alaskan Natives.

Methods

All Alaskan death certificates for 1980 through 1986 (N = 13,534) were reviewed. The underlying cause of death and all other conditions that contributed to the death as recorded on the death certificate were coded using the *Ninth International Classification of Diseases—Ninth Revision* (ICD-9). As a validation of the accuracy of coding, for deaths occurring during 1980–82, we manually verified our codes against those furnished by the National Center for Health Statistics (NCHS). Population estimates were obtained from the Alaska Department of Labor and the US Bureau of Census.[16] Alaskan Natives, consistent with designations of the Alaska Department of Labor and the US Bureau of Census, included Eskimo (Inupiaq and Yu'pik), American Indian (Athebaskan, Tlinqit, Haida, Tsimshian and other North American tribes), and Aleut.

We compared average annual death rates between Alaskan Natives and others according to major causes of death, using age-adjusted rates calculated by the direct method using the 1980 US Census as the standard. We compared cause-specific, age-adjusted death rates using the underlying cause of death, only, and by using contributory causes. Groupings of ICD codes are shown in Table 1 and the Appendix. Statistical analyses were done using Epi Info, Version 3, Division of Surveillance and Epidemiologic Studies, Epidemiology Program Office, Centers for Disease Control, Atlanta, Georgia.

Results

Alaskan Natives had a lower age-adjusted mortality rate from atherosclerosis and cardiovascular disease compared to other Alaskans (162.0 vs 242.1; RR = 0.67). Because the differences in death rates between underlying cause and multiple cause were so similar, only data for underlying cause are presented (Table 1). The only major difference in cardiovascular death rates by sex was for the comparison of ICD code 410, acute myocardial infarction, for underlying cause only, where female Natives had a slightly higher average annual, age-adjusted death rate than other females. For all other comparisons of cardiovascular disease-related groups, using underlying cause of death only, multiple causes, male, female, or total population, Alaskan Natives had consistently about 60 percent of the death rate of others.

In contrast, the death rates from infections, respiratory diseases, and neoplasms were all higher among Alaskan Natives than in others. The death rate from cardiovascular disease rose strikingly with age for both Natives and others (Figure 1) and was consistently present among the various cardiovascular-related disease, ICD code groups, by underlying cause and multiple cause, and in both males and females.

Interestingly, there was only one Native death due to aortic aneurysm (ICD code 441) compared to 88 deaths among others (RR = 23.8). The death rate due to all cerebrovascular disease (ICD codes 430–438) was slightly higher among Natives (RR = 1.08) and were primarily related to a higher rate of deaths due to cerebrovascular hemorrhage (ICD codes 430–432; RR = 1.36).

Discussion

This analysis of death certificate data provides additional evidence that arctic indigenous people have strikingly lower death rates from cardiovascular disease than others. The death rate due to cerebrovascular hemorrhage was slightly higher among Alaskan Natives than others, and similar to the overall difference in mortality rates between Natives and others. Other investigators have reported a high rate of cerebrovascular hemorrhage among Eskimos[14,17] and Japanese[18] who consumed high quantities of fish, raising concerns that increased use of dietary consumption of fish oils may lead to the unwanted consequence of cerebral hemorrhage. Our data do not support this concern.

Limitations of death certificates are well known.[19–22] No data exist about their accuracy in Alaska or the correlation of recorded causes of death with autopsy results. Autopsy

*Average annual age-adjusted rate per 100,000 by direct method to 1980 U.S. population.
**Native rate/Other rate

results, if available, were not routinely used to determine cause of death that was recorded on the death certificate by the attending physician. ICD coding was done by physician epidemiologists who were not trained nosologists but for another study and prior to involvement with work on diet and atherosclerosis—therefore, potential bias in coding cardiovascular related disease was minimized. We coded all death certificates because previous studies revealed many incorrectly coded certificates and because only the underlying cause of death had been coded. We analyzed our data using our codes; results using multiple cause coding were similar to results using underlying cause only. An analysis of NCHS codes using underlying cause only also showed similar results.
